Following a recent suggestion of axion cooling of photons between the nucleosynthesis and recombination epochs in the Early Universe, we investigate a hybrid model with both axions and relic supersymmetric particles. In this model we demonstrate that the 7Li abundance can be consistent with observations without destroying the important concordance of deuterium abundance.

The Hybrid Model – We carried out BBN network calculations using Kawano’s code [50, 51] by including Sarkar’s correction for 4He abundances [52]. JINA REACLIB Database V1.0 [53] is used for light nuclear (A ≤ 10) reaction rates including uncertainties together with data [54–56]. Adopted neutron lifetime is 878.5 ± 0.7stat ± 0.3sys s [57] based on improved measurements [48]. Taking into account the uncertainties in the rates of twelve important reactions in BBN [51], we employ regions of 95% C. L. in our calculations.

We compare our results with the abundance constraints from observations. For the primordial D abundance, the mean value estimated from Lyman-α absorption systems in the foreground of high redshift quasistellar objects is log(D/H) = −4.55 ± 0.03 [58]. We adopt this value together with a 2σ uncertainty, i.e., 2.45 × 10−5 < D/H < 3.24 × 10−5. 3He abundance measurements in Galactic HII regions through the 8.665 GHz hyperfine transition of 3He+ yield a value of 3He/H = (1.9 ± 0.6) × 10−5 [59]. Although the constraint should be rather weak considering its uncertainty, we take a 2σ upper limit and adopt 3He/H < 3.1 × 10−5.

We also utilize a limit on the sum of primordial abundances of D and 4He taken from an abundance for the protosolar cloud determined from observations of solar wind, i.e., (D+3He)/H=(3.6 ± 0.5) × 10−5 [60]. This abundance can be regarded as constant at least within the standard cosmology since it is not affected by stellar activities significantly despite an effect of D burning into 3He via 2H(p, γ)3He would exist [47].

For the primordial 4He abundance, we adopt two different constraints from recent reports: Yp = 0.2565 ± 0.0051 [61] and Yp = 0.2561 ± 0.0108 [62] both of which are derived from observations of metal-poor extragalactic HII regions. Adding 2σ uncertainties leads to 0.2463 < Yp < 0.2667 [61] and 0.2345 < Yp < 0.2777 [62].

6Li plateau of metal-poor halo stars (MPSs), yields the upper limit of 6Li/H = (7.1 ± 0.7) × 10−12 [6]. Adding a 2σ uncertainty, we adopt 6Li/H < 8.5 × 10−12.

Introduction – Low-metallicity halo stars exhibit a plateau of 7Li abundance, indicating the primordial origin of 7Li [1]. However, the amount of 7Li needed to be consistent with the cosmic microwave background observations [2] is significantly more than 7Li observed in old halo stars [3]. (Even though 7Li can be both produced and destroyed in stars, old halo dwarf stars are expected to have gone through little nuclear processing). Recent improvements in the observational and experimental data seem to make the discrepancy worse [4, 5]. One possible solution is to invoke either nuclear physics hinted to be excluded from the Big-Bang Nucleosynthesis (BBN) [6, 7] or new physics such as variations of fundamental couplings [8, 9], and particles not included in the Standard Model [10–42]. Effects of massive neutral relic particles on BBN were extensively studied [10–12].

More recently an alternative solution to the lithium puzzle was proposed. Since the last photon scattering occurs after the end of the nucleosynthesis, one can search for a mechanism for the cooling of photons before they decouple. It was suggested that dark matter axions could form a Bose-Einstein condensate (BEC) [13–15]. Such a condensate would cool the photons between the end of BBN and epoch of photon decoupling, reducing the baryon-to-photon ratio WMAP infers, as compared to its BBN value [15]. An alternative mechanism for such a cooling is resonant oscillations between photons and light abelian gauge bosons in the hidden sector [16]. There are two prima facie problems with the axion BEC-photon cooling hypothesis: it overpredicts primordial deuterium (D) abundance as well as the effective number of neutrinos. Even though D is easy to destroy, one does not expect the sum of abundances of D and 3He to change significantly in the course of cosmic evolution [17]. Hence it is important to find a parameter region in which predicted abundances of D and 7Li are consistent with observations. In this letter we demonstrate the existence of such a parameter region using a model with axions and massive relic particles.
For the $^7$Li abundance, we adopt the limits $\log(^7{\text{Li}}/H)= -12 + (2.199 \pm 0.086)$ (with 95% C. L.) derived from recent observations of MPHSs in the 3D nonlocal thermal equilibrium model [63], i.e. $1.06 \times 10^{-10} < ^7{\text{Li}}/H < 2.35 \times 10^{-10}$.

Figure 1 shows the abundances of $^4$He ($Y_p$; mass fraction), D, $^3$He, $^7$Li and $^6$Li (number ratio relative to H) as a function of the baryon-to-photon ratio $\eta$ or the baryon energy density parameter $\Omega_B h^2$ of the universe, where $h$ is the Hubble constant in units of 100 km/s/Mpc. The thick dashed curves are the results of the standard BBN (SBBN) with a neutron lifetime of $878.5 \pm 0.8$ s. Thin dashed curves around them show regions of 95% C. L. from uncertainties in the nuclear reaction rates. The boxes represent adopted abundance constraints as summarized above. The vertical stripes correspond to the 2$\sigma$ limits on $\Omega_B h^2$ or $\eta$. The values provided by WMAP [49] (labeled WMAP7) are

$$\Omega_B h^2 = 0.02258^{+0.00114}_{-0.00112} \eta = (6.225^{+0.314}_{-0.305}) \times 10^{-10}. \quad (1)$$

Values predicted by the BEC model (labeled axion) are smaller by a factor of $(2/3)^{3/4}$ at the BBN epoch [45]:

$$\Omega_B h^2 = 0.01666^{+0.00084}_{-0.00083} \eta = (4.593^{+0.232}_{-0.225}) \times 10^{-10}. \quad (2)$$

It can be seen that the adoption of the $\eta$ value from WMAP leads to a $^7$Li abundance calculated in the axion BEC model, which is in reasonable agreement with the observations. However, we lose the important consistency in D abundance. Ref. [45] noted that astronomical measurements of primordial D abundance can have a significant uncertainty as well as a possibility that D is burned by nonstandard stellar processes. Even if their assumption were true, stellar processes are not expected to change the sum of D and $^3$He abundances [47]. As seen in Fig. 1, the constraint on $(D+^3\text{He})/H$ abundance seems to exclude the original axion BEC model. Ultimately, this model is viable only when the abundance of $(D+^3\text{He})/H$ is reduced through some exotic processes.

It is known that nonthermal photons can be generated through electromagnetic energy injections by the radiative decay of long-lived particles after the BBN epoch [11, 16]. These nonthermal photons can photodisintegrate background light elements [10, 11, 10, 20, 24, 25]. We adopt the method of Ref. [25] to calculate the nonthermal nucleosynthesis, where we incorporated new thermal reaction rates as described above. In addition, we adopt updated reaction rates of $^4$He photodisintegration [24] derived from the cross section data using precise measurements with laser-Compton photons [63, 65]. Effects of electromagnetic energy injection depend on two parameters. One is $\zeta_X = (n_X/n_H)E_{50}$ where $(n_X/n_H)$ is the number ratio of the decaying particle $X$ and the background radiation before the decay of $X$, and $E_{50}$ is the energy of photon emitted at the radiative decay. The other is $\tau_X$, the lifetime of the $X$ particle. The thick dashed curves are the results of the standard BBN (SBBN) with a neutron lifetime of $878.5 \pm 0.8$ s. Thin dashed curves around them show regions of 95% C. L. from uncertainties in the nuclear reaction rates. The boxes represent adopted abundance constraints as summarized above. The vertical stripes correspond to the 2$\sigma$ limits on $\Omega_B h^2$ or $\eta$. The values provided by WMAP [49] (labeled WMAP7) are
Primordial D abundance via drawback of the original axion BEC model by reducing We conclude that the present model eliminates the main recently in ranges of adopted observational constraints. Abundance of all nuclides including D and 7\(^\text{Li}\) constraints. The orange line is the contour of \(7\text{Li}/H=7.1 \times 10^{-12}\). In the gray-colored region all abundances are within the limits of observational constraints.

In the very small colored region, calculated primordial abundances of all nuclides including D and 7\(^\text{Li}\) are simultaneously in ranges of adopted observational constraints. We conclude that the present model eliminates the main drawback of the original axion BEC model by reducing primordial D abundance via \(^2\text{H}(\gamma, n)^3\text{H}\) reaction, where \(\gamma\)'s are nonthermal photons. We note that the decaying particle model with the WMAP \(\eta\) value cannot resolve the 7\(^\text{Li}\) problem by itself \(23, 25\).

The effect of the radiative decay on other elemental abundances is not significant except for 7\(^\text{Li}\). Since energetic photons produced quickly collide with background photons and create \(e^+ e^-\) pairs, nonthermal photon spectra developed by the decay has a cutoff energy \(E_C = m_e^2/22T\) where \(m_e\) is the electron mass \(10\). The decay at earlier (hotter) universe then triggers nonthermal photons with lower cutoff energies. The threshold energies of \(^7\text{Be}\) and D photodisintegration, \(^7\text{Be} + \gamma \rightarrow ^{4}\text{He} + ^4\text{He}\) and \(D + \gamma \rightarrow n + p\) are 1.5866 MeV and 2.2246 MeV, respectively. These two nuclei are very fragile against photodisintegration. When the decay occurs early at relatively high \(T_9 \equiv T/(10^9 \text{ K}) \geq 10^{-2}\) which corresponds to \(\tau_X \lesssim 10^6 \text{ s}\), nonthermal photon spectra contain photons to dissociate \(^7\text{Be}\) and D, while keeping other nuclides intact. The gray region indicates parameters which result in moderate destruction of D which is overproduced in the original BEC model because of low \(\eta\). Above that region, D is destroyed too much by photodisintegration, while below it D abundance is too high.

We next present the results of a BBN calculation in our hybrid model with a fixed set of parameters given by \((\tau_X, \zeta_X)=(10^6 \text{ s}, 2 \times 10^{-10} \text{ GeV})\) and the \(\eta\) value given in Eq. \(2\). This corresponds to the point indicated with a star in Fig. \(2\) and yields the required D and \(^7\text{Li}\) abundances as seen in Figure \(3\). This figure shows H and \(^4\text{He}\) mass fractions (denoted by \(X_p\) and \(Y_p\)), and \(n, D, T, ^3\text{He}, ^6\text{Li}, ^7\text{Li}\), and \(^7\text{Be}\) number ratios relative to H as a function of the temperature. The abundances calculated using the axion BEC + long-lived decaying particle model with the parameters \((\tau_X, \zeta_X)=(10^6 \text{ s}, 2 \times 10^{-10} \text{ GeV})\) and the \(\eta\) value provided by BEC model [Eq. \(2\)] are shown in solid lines whereas the SBBN prediction is plotted by dashed lines. The small difference at \(T_9 \lesssim 0.06\) observed between solid and dashed lines is caused by difference between initial \(\eta\) values. At \(0.06 \lesssim T_9 \lesssim 7 \times 10^{-3}\) (corresponding to the cosmic time of \(t \sim 5 \times 10^4\)--4 \times 10^6 \text{ s}), effects of \(^2\text{H}(\gamma, n)^3\text{H}\) are seen in the decrease of D and the increase of \(n\) abundances. We find a slight decrease in \(^7\text{Be}\) abundance. This is caused through reactions \(^7\text{Be}(\gamma, ^4\text{He})^4\text{He}\) (threshold energy: 1.5866 MeV), \(^7\text{Be}(\gamma, p)^6\text{Li}\) (5.6858 MeV), and \(^7\text{Be}(\gamma, 2\text{pn})^4\text{He}\) (9.3047 MeV). The second reaction increases the \(^6\text{Li}\) abundance. Finally, at \(T_9 \lesssim 7 \times 10^{-3}\), where the abundance of long-lived \(X\) particle is already less than 3 \% of the initial abundance, effect of \(^4\text{He}\) photodisintegration is to increase \(^4\text{H}\) and \(n\) abundances.

In Fig. \(4\) solid lines show the results for the SBBN + long-lived decaying particle model with the same parameter values, i.e., \((\tau_X, \zeta_X)=(10^6 \text{ s}, 2 \times 10^{-10} \text{ GeV})\). Obviously the abundances of D and \(^7\text{Li}\) (produced partly as \(^7\text{Be}\)) are reduced, while that of \(^6\text{Li}\) is increased from those of SBBN.
Conclusions – We used a hybrid axion and massive relic particle model in which axions cool the photons and relic particles produce non-thermal photons to eliminate the high $D$ abundance in the original axion BEC model. Our hybrid model also produces $^6\text{Li}$ keeping $^7\text{Li}$ abundance at the level of Population II Spite plateau. Our work thus demonstrates that the $^7\text{Li}$ abundance can be consistent with observations without destroying the important concordance of deuterium abundance.
