Abstract

Conversions and semi-annihilations of dark matter (DM) particles in addition to the standard DM annihilations are considered in a three-component DM system. We find that the relic abundance of DM can be very sensitive to these non-standard DM annihilation processes, which has been recently found for two-component DM systems. To consider a concrete model of a three-component DM system, we extend the radiative seesaw model of Ma by adding a Majorana fermion $\chi$ and a real scalar boson $\phi$, to obtain a $Z_2 \times Z'_2$ DM stabilizing symmetry, where we assume that the DM particles are the inert Higgs boson, $\chi$ and $\phi$. It is shown how the allowed parameter space, obtained previously in the absence of $\chi$ and $\phi$, changes. The semi-annihilation process in this model produces monochromatic neutrinos. The observation rate of these monochromatic neutrinos from the Sun at IceCube is estimated. Observations of high energy monochromatic neutrinos from the Sun may indicate a multi-component DM system.

I. INTRODUCTION

Recent astrophysical observations [1–3] have made it clear that most of the energy of the Universe consists of dark energy and cold dark matter (DM), and their portions are very well fixed by these observations. While the origin of dark energy might be the cosmological constant of Einstein, the origin of cold DM cannot be found within the framework of the standard model (SM) of elementary particles. Moreover, we do not know very much about the detailed features of DM at present, even if the origin of DM should be elementary particles. Currently, many experiments are undertaken or planned, and it is widely believed that the existence of DM will be independently confirmed in the near future (see, for instance, Refs. [4–6]).

A particle DM candidate can be made stable by an unbroken symmetry. The simplest possibility of such a symmetry is a parity, $Z_2$. Whatever the origin of the $Z_2$ is, the lightest $Z_2$-odd particle can be a DM candidate if it is a neutral, weakly interacting and massive particle (WIMP) (see Ref. [5] for a review). There are a variety of origins of the $Z_2$, $R$ parity in the minimal supersymmetric standard model (MSSM), which is introduced to forbid fast proton decay, is a well-known example (see Ref. [4] for a review). In this paper, we consider a universe consisting of stable multi-DM particles [7]–[29]. A multi-component DM system can be realized if the DM stabilizing symmetry is larger than $Z_2$: $Z_N$ ($N \geq 4$) or a product of two or more $Z_2$’s can yield a multi-component DM system.

In a supersymmetric extension of the radiative seesaw model of Ref. [32], for instance, a $Z_2 \times Z'_2$ symmetry appears, providing various concrete models of multi-component DM systems [25]–[29].

In a multi-component DM system, there can be various DM annihilation processes that are different from the standard DM annihilation process [33]–[38], $\text{DM DM} \rightarrow XX$, where $X$ is a generic SM particle in thermal equilibrium. Even in one-component DM systems, the non-standard annihilation process, the co-annihilation of DM and a nearly degenerate unstable particle [39], can play a crucial role in the MSSM [40]. The importance of non-standard annihilation processes such as DM conversion [17, 22, 23] and semi-annihilation of DM [17, 23] in two-component DM systems for the temperature evolution of the number density of DM has been recently reported.

If $(Z_2)^\ell$ is unbroken, there can exist at least $K = \ell$ stable DM particles. In a kinematically fortunate situation, $2^\ell - 1$ stable DM particles can exist; for $\ell = 2$ there can be maximally $K = 3$ stable DM particles. Any one-component DM model can easily be extended to a multi-component DM system. The allowed parameter space of a one-component DM model can considerably change, as has been recently found in Ref. [29] (see also Ref. [10]), even using a crude approximation of a DM conversion process in a supersymmetric extension of the radiative seesaw model.

In Sec. II, after outlining a derivation of the coupled Boltzmann equations that are ap-

\footnote{Z_3 allows only one-component DM systems. Refs. [30, 31] discuss models with Z_3.}
appropriate for our purpose, we consider fictive two- and three-component DM systems and analyze the effects of non-standard annihilation processes of DM. In Sec. III we extend the radiative seesaw model of Ref. [32] by adding an extra Majorana fermion $\chi$ and an extra real scalar boson $\phi$, so as to obtain $Z_2 \times Z'_2$ as a DM stabilizing symmetry. Apart from the presence of $\phi$, the Higgs sector is identical to that of Refs. [41–43]. This model shows how the allowed parameter space, which is obtained in Refs. [41–43] under the assumption that the lightest inert Higgs boson is DM, can change. Indirect detection of DM—in particular, of neutrinos from the annihilation of the captured DM in the Sun [44–53]—is also discussed. We solve the coupled evolution equations of the DM numbers in the Sun, which describe approaching equilibrium between the capture and annihilation (including conversion and semi-annihilation) rates of DM, and estimate the observation rates of neutrinos. Due to semi-annihilations of DM, monochromatic neutrinos are radiated from the Sun. Our conclusions are given in Sec. IV.

II. THE BOLTZMANN EQUATION AND TWO- AND THREE-COMPONENT DM SYSTEMS

A. The Boltzmann equation

Here we would like to outline a derivation of the Boltzmann equation that we are going to apply in the next section. We will do it for completeness, although the following discussion partially parallels that of Ref. [17] (see also Ref. [22]). We start by assuming the existence of $K$ stable DM particles $\chi_i$ with mass $m_i$. None of the DM particles have the same quantum number with respect to the DM stabilizing symmetry. All the other particles are supposed to be in thermal equilibrium. Then we restrict ourselves to three types of processes which enter the Boltzmann equation:

\begin{align*}
\chi_i \chi_i & \leftrightarrow X_i X'_i , \quad (1) \\
\chi_i \chi_i & \leftrightarrow \chi_j \chi_j \text{ (DM conversion)} , \quad (2) \\
\chi_i \chi_j & \leftrightarrow \chi_k X_{ijk} \text{ (DM semi-annihilation)} , \quad (3)
\end{align*}

where the extension to include coannihilations and annihilation processes like $\chi_i + \chi_j \leftrightarrow \chi_k + \chi_l$ is straightforward. See Fig. 1 for a depiction of DM conversion and DM semi-annihilation.

We denote the phase space density of $\chi_i$ by $f_i(E_i, t)$ and its number density by $n_i(t) = (g/(2\pi^3))^3 \int d^3 p_i f_i(E_i, t)$, where $g$ stands for the internal degrees of freedom. Then the density $n_i$ satisfies the Boltzmann equation (see, e.g., Ref. [36]), which we will not spell out here. Instead, we make the replacement

\begin{equation}
t = 0.301 g_*^{-1/2} M_{\text{PL}} T^{-2} , \quad (4)
\end{equation}
during the radiation-dominated epoch, where $t$ is the time of the comoving frame, $g_*$ is the total number of effective degrees of freedom, and $T$ and $M_{\text{Pl}}$ are the temperature and the Planck mass, respectively. Further, we use the approximation

$$f_i(E_i, t) \approx \bar{n}_i(t),$$

where $\bar{f}_i(E_i, t) \approx \exp(-E_i/T)$ and $\bar{n}_i = (g/(2\pi)^3) \int d^3 p_i \bar{f}_i(E_i, t)$ are the values in equilibrium, and we ignore the chemical potential. Then the collision terms in the Boltzmann equation can be written as

$$-(\text{PSI})|M(ii; Xi X'_i)|^2 \frac{\bar{f}_i \bar{f}_{i'}}{\bar{n}_i \bar{n}_i} (n_i n_i - \bar{n}_i \bar{n}_i),$$

$$- \sum_{i>j}(\text{PSI}) |M(ii; jj)|^2 \frac{\bar{f}_i \bar{f}_j}{\bar{n}_i \bar{n}_i} (n_i n_i - \frac{n_j n_j}{\bar{n}_i \bar{n}_i})$$

$$+ \sum_{j>i}(\text{PSI}) |M(jj; ii)|^2 \frac{\bar{f}_j \bar{f}_j}{\bar{n}_j \bar{n}_j} (n_j n_j - \frac{n_i n_i}{\bar{n}_j \bar{n}_j}),$$

$$- \sum_{j,k}(\text{PSI}) |M(ij; kX_{ijk})|^2 \frac{\bar{f}_i \bar{f}_k}{\bar{n}_i \bar{n}_k} \left( n_i n_j - \frac{n_k}{\bar{n}_i} \bar{n}_j \right),$$

$$+ \sum_{j,k}(\text{PSI}) |M(jk; iX_{jkl})|^2 \frac{\bar{f}_j \bar{f}_k}{\bar{n}_j \bar{n}_k} \left( n_j n_k - \frac{n_i}{\bar{n}_j} \bar{n}_k \right),$$

where PSI stands for "phase space integral of $(2\pi)^4 \delta^4$(momenta)\times", $M$ is the matrix element of the corresponding process, and we have assumed that

$$m_i \geq m_j \text{ for } i > j \text{ and } m_{Xi}, m_{X'i}, m_{X_{ijk}} << m_I \text{ for all } i, j, k, l.$$  

Using the notion of the thermally averaged cross section,

$$< \sigma(ii; X_i X'_i)v > = \frac{1}{\bar{n}_i \bar{n}_i} \text{PSI}|M(ii; X_i X'_i)|^2 \bar{f}_i \bar{f}_i,$$
and the dimensionless inverse temperature \( x = \mu / T \), we obtain for the number per comoving volume, \( Y_i = n_i / s \):

\[
\frac{dY_i}{dx} = -0.264 \, g^*_{s}^{1/2} \left[ \frac{\mu M_{PL}}{x^2} \right] \left\{ \langle \sigma (ii; X_i X_i') \rangle v > \left( Y_i Y_i - \bar{Y}_i \bar{Y}_i \right) + \sum_{i>j} <\sigma (ii; jj) v > \left( Y_i Y_j - \frac{Y_j Y_i}{Y_j Y_j} \bar{Y}_i \bar{Y}_j \right) \right. \\
+ \left. \sum_{j,k} <\sigma (ij; kX_{ijk}) v > \left( Y_i Y_j - \frac{Y_k Y_i}{Y_k Y_k} \bar{Y}_j \bar{Y}_j \right) \right. \\
+ \left. \left. \sum_{j,k} <\sigma (jk; iX_{jki}) v > \left( Y_j Y_k - \frac{Y_i Y_k}{Y_i Y_i} \bar{Y}_j \bar{Y}_k \right) \right\} , \tag{9}
\]

where \( 1 / \mu = (\sum_i m_i^{-1}) \) is the reduced mass of the system. To arrive at Eq. \( \text{(9)} \), we have used \( s = (2\pi^2 / 45) g_s T^3 \), \( H = 1.66 \times g^*_{s}^{1/2} T^2 / M_{PL} \), where \( s \) is the entropy density and \( H \) is the Hubble constant.

We will integrate this system of coupled non-linear differential equations numerically. Before we apply the Boltzmann equation [Eq. \( \text{(9)} \)] to a concrete DM model, we discuss below the cases of \( K = 2 \) and 3, simply assuming fictitious values of the thermally averaged cross sections and DM masses \( m_i \).

### B. Two-component DM system

Before we come to one of our main interests, a three-component DM system, we first consider the \( K = 2 \) case with a \( Z_2 \times Z_2' \) symmetry. In this case, there are three different thermally averaged cross sections. No semi-annihilation [Eq. \( \text{(3)} \)] is allowed due to \( Z_2 \times Z_2'. \)

We further assume that there are only \( s \)-wave contributions to \( \langle \sigma v \rangle \) and that \( X_i (i = 1, 2) \) are massless while \( m_1 \geq m_2 \):

\[
\langle \sigma (11; X_1 X_1') v > = \sigma_{0.1} \times 10^{-9} \text{ GeV}^{-2} , \quad \langle \sigma (22; X_2 X_2') v > = \sigma_{0.2} \times 10^{-9} \text{ GeV}^{-2} , \\
\langle \sigma (11; 22) v > = \sigma_{0.12} \times 10^{-9} \text{ GeV}^{-2} . \tag{10}
\]

Equation \( \text{(9)} \) then becomes

\[
\frac{dY_1}{dx} = -0.264 \, g^*_{s}^{1/2} \left[ \frac{\mu M_{PL}}{x^2} \right] \left\{ \langle \sigma (11; X_1 X_1') \rangle v > \left( Y_1 Y_1 - \bar{Y}_1 \bar{Y}_1 \right) \right\} , \tag{11}
\]

\[
\frac{dY_2}{dx} = -0.264 \, g^*_{s}^{1/2} \left[ \frac{\mu M_{PL}}{x^2} \right] \left\{ \langle \sigma (22; X_2 X_2') \rangle v > \left( Y_2 Y_2 - \bar{Y}_2 \bar{Y}_2 \right) \right. \\
- \left. \langle \sigma (11; 22) \rangle v > \left( \frac{Y_2 Y_2}{Y_2 Y_2} \bar{Y}_1 \bar{Y}_1 \right) \right\} . \tag{12}
\]

\(^{2}\) In Refs. \[17, 23\], the \( Z_4 \) case is discussed in detail. In this case there exist two independent DM particles, because due to CP invariance, the anti-particle is not an independent degree of freedom in the Boltzmann equation. Semi-annihilation is allowed in this case.
the density of relic abundance $\Omega_T^\chi_m$ of $\chi$ or 0 (dashed curves), averaged cross sections, if we assume that $m$ parametrizes the size of the DM conversion, Eq. (2)), $\Omega_T^\chi_m$ of critical densities, $\Omega_T^\chi_m$ are of similar order (see also Ref. [22]). In Fig. 2 (left), we show the evolution of the fraction curves), , Refs. [12, 17, 22, 23].

As we have noticed before, the $K = 3$ case is possible even for a $Z_2 \times Z_2'$ symmetry if the decay of $\chi_1$ is kinematically forbidden. In this case, there are nine different thermally-averaged cross sections, if we assume that $m_1 \geq m_2 \geq m_3$ and $m_2 + m_3 > m_1$:

\begin{align*}
<\sigma(\text{i}; X,X')v> &= \sigma_{0,i} \times 10^{-9} \text{ GeV}^{-2}, \quad <\sigma(11; 22)v> = \sigma_{0,12} \times 10^{-9} \text{ GeV}^{-2}, \\
<\sigma(11; 33)v> &= \sigma_{0,13} \times 10^{-9} \text{ GeV}^{-2}, \quad <\sigma(22; 33)v> = \sigma_{0,23} \times 10^{-9} \text{ GeV}^{-2}, \\
<\sigma(12; 3X_{123})v> &= \sigma_{0,123} \times 10^{-9} \text{ GeV}^{-2}, \quad <\sigma(23; 1X_{231})v> = \sigma_{0,231} \times 10^{-9} \text{ GeV}^{-2},
\end{align*}

We consider the case in which the size of the DM conversion and the standard annihilation are of similar order (see also Ref. [22]). In Fig. 2 (left), we show the evolution of the fraction of critical densities, $\Omega_{\chi_1}^\chi_m h^2(x)$ (black curves) and $\Omega_{\chi_2}^\chi_m h^2(x)$ (blue curves), contributed by $\chi_1$ and $\chi_2$, respectively, where we have used $\sigma_{0,1} = 0.1$, $\sigma_{0,2} = 6$, $\sigma_{0,12} = 4.4$ (solid curves) or 0 (dashed curves), $m_1 = 200$ GeV, $m_2 = 160$ GeV and $g_* = 90$, and $x = \mu/T = [(m_1^{-1} + m_2^{-1})T]^{-1}$. As we see from Fig. 2 (left), at $\sigma_{0,12} = 0$ (i.e., no DM conversion, Eq. (2)), the density of $\chi_1$ decouples from the equilibrium value for smaller $x$ than the density of $\chi_2$ does. This is because we have chosen a small value for $\sigma_{0,1}$ and a large value for $\sigma_{0,2}$. At $\sigma_{0,12} = 0$, $\Omega_{\chi_1}^\chi_m h^2 \approx 1.99$, while $\Omega_{\chi_2}^\chi_m h^2 \approx 0.04$. With increasing value of $\sigma_{0,12}$ (which parametrizes the size of the conversion, Eq. (2)), $\Omega_{\chi_1}^\chi_m h^2$ decreases, while $\Omega_{\chi_2}^\chi_m h^2$ increases. Around $\sigma_{0,12} = 3.9$, this order changes, i.e., $\Omega_{\chi_1}^\chi_m < \Omega_{\chi_2}^\chi_m$. At $\sigma_{0,12} = 4.4$, we obtain the total relic abundance $\Omega_T^\chi_m h^2 = \Omega_{\chi_1}^\chi_m h^2 + \Omega_{\chi_2}^\chi_m h^2 = 0.112$, in accord with the WMAP observation $\Omega_T^\chi_m h^2 = 0.1126 \pm 0.0036$ [3]. In Fig. 2 (right), we plot $\Omega_T^\chi_m h^2$ as a function of $\sigma_{0,12}$. We see that the DM conversion process plays an important role, as has also been found in Refs. [12, 17, 22, 23].

C. Three-component DM system

As we have noticed before, the $K = 3$ case is possible even for a $Z_2 \times Z_2'$ symmetry if the decay of $\chi_1$ is kinematically forbidden. In this case, there are nine different thermally-averaged cross sections, if we assume that $m_1 \geq m_2 \geq m_3$ and $m_2 + m_3 > m_1$:

\begin{align*}
<\sigma(\text{i}; X,X')v> &= \sigma_{0,i} \times 10^{-9} \text{ GeV}^{-2}, \quad <\sigma(11; 22)v> = \sigma_{0,12} \times 10^{-9} \text{ GeV}^{-2}, \\
<\sigma(11; 33)v> &= \sigma_{0,13} \times 10^{-9} \text{ GeV}^{-2}, \quad <\sigma(22; 33)v> = \sigma_{0,23} \times 10^{-9} \text{ GeV}^{-2}, \\
<\sigma(12; 3X_{123})v> &= \sigma_{0,123} \times 10^{-9} \text{ GeV}^{-2}, \quad <\sigma(23; 1X_{231})v> = \sigma_{0,231} \times 10^{-9} \text{ GeV}^{-2},
\end{align*}
\[<\sigma(31; 2X_{312})v> = \sigma_{0.312} \times 10^{-9} \text{ GeV}^{-2}.\]  

Equation (9) then becomes

\[
\frac{dY_1}{dx} = -0.264 \ g^*/2 \left[ \frac{\mu_{\text{PL}}}{x^2} \right] \left\{ <\sigma(11; X_1X_1')v> (Y_1Y_1 - \bar{Y}_1\bar{Y}_1) + <\sigma(11; 22)v> (Y_1Y_1 - \frac{Y_2Y_2}{Y_3Y_3} Y_3\bar{Y}_1) \right.
+ <\sigma(11; 33)v> (Y_1Y_1 - \frac{Y_2Y_2}{Y_3Y_3} Y_3\bar{Y}_1)
+ <\sigma(12; 3X_{123})v> (Y_1Y_2 - \frac{Y_2Y_2}{Y_3Y_3} Y_3\bar{Y}_2)
+ <\sigma(12; 3X_{123})v> (Y_1Y_2 - \frac{Y_2Y_2}{Y_3Y_3} Y_3\bar{Y}_2) - <\sigma(31; 2X_{312})v> (Y_1Y_3 - \frac{Y_2Y_2}{Y_3Y_3} Y_3\bar{Y}_3)
\]

\[\left. - <\sigma(23; 1X_{231})v> (Y_3Y_2 - \frac{Y_1Y_1}{Y_3Y_3} Y_3\bar{Y}_2) \right\}, \tag{14}\]

\[
\frac{dY_2}{dx} = -0.264 \ g^*/2 \left[ \frac{\mu_{\text{PL}}}{x^2} \right] \left\{ <\sigma(22; X_2X_2')v> (Y_2Y_2 - \bar{Y}_2\bar{Y}_2) + <\sigma(22; 33)v> (Y_2Y_2 - \frac{Y_3Y_3}{Y_1Y_1} Y_1\bar{Y}_2)
+ <\sigma(22; 33)v> (Y_2Y_2 - \frac{Y_3Y_3}{Y_1Y_1} Y_1\bar{Y}_2) - <\sigma(31; 2X_{312})v> (Y_1Y_3 - \frac{Y_2Y_2}{Y_3Y_3} Y_3\bar{Y}_3)
\]

\[\left. - <\sigma(11; 22)v> (Y_1Y_3 - \frac{Y_2Y_2}{Y_3Y_3} Y_3\bar{Y}_3) \right\}, \tag{15}\]

\[
\frac{dY_3}{dx} = -0.264 \ g^*/2 \left[ \frac{\mu_{\text{PL}}}{x^2} \right] \left\{ <\sigma(33; X_3X_3')v> (Y_3Y_3 - \bar{Y}_3\bar{Y}_3)
+ <\sigma(33; X_3X_3')v> (Y_3Y_3 - \frac{Y_1Y_1}{Y_3Y_3} Y_3\bar{Y}_3)
+ <\sigma(31; 2X_{312})v> (Y_1Y_3 - \frac{Y_2Y_2}{Y_3Y_3} Y_3\bar{Y}_3)
\]

\[\left. - <\sigma(22; 33)v> (Y_2Y_3 - \frac{Y_3Y_3}{Y_1Y_1} Y_1\bar{Y}_3) \right\}, \tag{16}\]

where \(1/\mu = 1/m_1 + 1/m_2 + 1/m_3.\)

As a representative example, we consider the following set of input values of the parameters:

\[
m_1 = 200 \text{ GeV} , \ m_2 = 160 \text{ GeV} , \ m_3 = 140 \text{ GeV} ,
\]

\[
\sigma_{0.1} = 0.1 , \ \sigma_{0.2} = 2 , \ \sigma_{0.3} = 6 . \tag{17}\]

First, we show the evolution of \(\Omega_{\chi_i} h^2(x)\) in Fig. 4 (left) for \(\sigma_{0.12} = 0.13 = \sigma_{0.23} = \sigma_{0.023} = \sigma_{0.312} = \sigma_{0.231} = 0,\) which corresponds to the situation without the non-standard annihilation processes. Since \(m_1 > m_2, m_3,\) and the cross section \(\sigma(11; X_1X_1)\) is small in this example, the relic abundance of \(\chi_1\) is large compared with that of \(\chi_2\) and \(\chi_3.\) This changes if we switch on the non-standard annihilation processes. This is shown in Fig. 4 (right), where we have used \(\sigma_{0.12} = 0.13 = \sigma_{0.23} = 5.2,\) while \(\sigma_{0.123} = \sigma_{0.312} = \sigma_{0.231} = 0,\) to show the effects of \(\chi_1\chi_1 \leftrightarrow \chi_j\chi_j\)-type processes (DM conversion). As expected, the relic abundances of \(\chi_1\) and \(\chi_2\) decrease and drop below 0.1, while that of \(\chi_3\) does not change very much.
FIG. 3: The relic abundance $\Omega_{\chi_1}h^2(x)$ (black curve), $\Omega_{\chi_2}h^2(x)$ (blue curve) and $\Omega_{\chi_3}h^2(x)$ (red curve) as a function of $x = \mu/T = [(m_1^{-1} + m_2^{-1} + m_3^{-1})T]^{-1}$, where the input parameters are given in Eq. (17). Left: Without the non-standard annihilation processes [Eqs. (2) and (3)]. Right: $\sigma_{0,12} = \sigma_{0,13} = \sigma_{0,23} = 5.2$, while $\sigma_{0,123} = \sigma_{0,312} = \sigma_{0,231} = 0$, to see the effects of $\chi_i\chi_i \leftrightarrow \chi_j\chi_j$ type processes [Eq. (3)].

FIG. 4: The relic abundance $\Omega_{\chi_1}h^2(x)$ (black curve), $\Omega_{\chi_2}h^2(x)$ (blue curve) and $\Omega_{\chi_3}h^2(x)$ (red curve) as a function of $x$ with $\sigma_{0,12} = \sigma_{0,13} = \sigma_{0,23} = 0$, while $\sigma_{0,123} = \sigma_{0,312} = \sigma_{0,231} = 5.1$, to show the effects of $\chi_i\chi_j \leftrightarrow \chi_kX_{ijk}$ type processes [Eq. (3)].

Figure 4 shows the evolution of $\Omega_{\chi_i}h^2(x)$ for $\sigma_{0,12} = \sigma_{0,13} = \sigma_{0,23} = 0$, while $\sigma_{0,123} = \sigma_{0,312} = \sigma_{0,231} = 5.1$, to show the effects of $\chi_i\chi_j \leftrightarrow \chi_3X_{ij3}$-type processes (semi-annihilation). It is interesting to observe that the order of the relic abundances changes, and $\Omega_{\chi_1}h^2(x)$ first decreases as usual, but then starts to increase towards the freeze-out value. So, the effects of $\chi_i\chi_i \leftrightarrow \chi_j\chi_j$-type and $\chi_i\chi_j \leftrightarrow \chi_kX_{ijk}$-type processes are different. In the examples above, $\sigma_{0,ij}$ and $\sigma_{0,ijk}$ are chosen such that the total abundance $\Omega_T h^2$ becomes about the realistic value 0.112. In Fig. 5, we show the total abundance $\Omega_T h^2$ as a function of $\sigma_{0,ij}$ (solid curve) and $\sigma_{0,ijk}$ (dashed curve), where $\sigma_{0,ij}$ parameterizes the size of the DM conversion [Eq. (2)] and $\sigma_{0,ijk}$ parameterizes the size of the semi-annihilation [Eq. (3)]. As we can see from Fig. 5, only for small values of $\sigma_{0,ij}$ and $\sigma_{0,ijk}$ are the effects on $\Omega_T h^2$ different.
FIG. 5: The total relic abundance $\Omega T h^2$ as a function of $\sigma_{0,12}$ (solid curve) and $\sigma_{0,123}$ (dashed curve). Except $\sigma_{0,12}$ (DM conversion) and $\sigma_{0,123}$ (semi-annihilation), the input parameters are given in Eq. (17).

TABLE I: The relic abundances for the symmetric case of $\sigma_{0,ijk}$; i.e., $\sigma_{0,123} = \sigma_{0,231} = \sigma_{0,312}$, with $m_1 = 1000 \text{ GeV}$.

Note that the dark matter conversion process [Eq. (2)] is dark-matter-number conserving, while the semi-annihilation process [Eq. (3)] is not. Next, we would like to consider an extreme case where only semi-annihilations are present, and as before we assume that $m_1 \geq m_2 \geq m_3$ and $m_2 + m_3 > m_1$. In Table I, we show various examples of the individual relic abundances with $m_1$ fixed at 1000 GeV, where we have assumed that the value of $\sigma_{0,ijk}$ is the same independent of $i, j$ and $k$. These values are chosen such that the total relic abundance is consistent with $\Omega T h^2 = 0.1126 \pm 0.0036$. As we see from Table I, depending on the hierarchy of the dark matter masses, the value of $\sigma_{0,123}$ has to be tuned to obtain the observed value of the total relic abundance. We may say that the more hierarchical the dark matter masses are, the larger $\sigma_{0,123}$ is, and the larger $\Omega_{\chi_3} h^2$ is. We then consider the asymmetric case, i.e., $\sigma_{0,123} \neq \sigma_{0,231} \neq \sigma_{0,312}$. In Table II, we give some examples of this case with fixed dark matter masses, $m_1 = 1000 \text{ GeV}$, $m_2 = 900 \text{ GeV}$ and $m_3 = 550 \text{ GeV}$, where we have assumed that $m_1$ and $m_2$ are close, but $m_3$ is about one half of $m_1$. Since $\sigma_{0,123}$ is the size for the semi-annihilation $\chi_1 \chi_2 \rightarrow \chi_3 X$, the relic abundance of $\chi_3$ is larger than the others for larger $\sigma_{0,123}$. Finally, we would like to point out that, since each semi-annihilation produces a DM particle, the semi-annihilation process can be few orders of magnitude larger than the standard process where only the standard process exists (as we
TABLE II: The relic abundances for the asymmetric case; i.e., \( \sigma_{0,123} \neq \sigma_{0,231} \neq \sigma_{0,312} \), with \( m_1 = 1000 \) GeV, \( m_2 = 900 \) GeV and \( m_3 = 550 \) GeV.

can see from Tables I and II). The magnitude, of course, depends on a model, but this can be a useful information for model building.

### III. A MODEL WITH THREE DARK MATTER PARTICLES

We extend the original radiative seesaw model of Ref. [32] so as to have an additional discrete symmetry, \( Z'_2 \). This can be done by introducing a SM singlet Majorana fermion \( \chi \) and a SM singlet real inert scalar \( \phi \) in addition to the inert Higgs doublet \( \eta \) which is present in the original model. The matter content of the model with the corresponding quantum numbers is given in Table III.

The \( Z_2 \times Z'_2 \) invariant Yukawa couplings of the lepton sector are given by

\[
\mathcal{L}_Y = Y_{ij}^e H^1 l_i l_j^c + Y_{ik}^\nu L_i \eta N_k^c + Y_{k}^\chi \chi N_k^c \phi + h.c. ,
\]

and the Majorana mass terms of the right-handed neutrinos \( N_k^c \) \((k = 1, 2, 3)\) and the singlet
The fermion $\chi$ are\(^3\)

$$L_{\text{Maj}} = \frac{1}{2} M_k N_k^c N_k^\dagger + \frac{1}{2} M_\chi \chi^2 + \text{h.c.} \quad (19)$$

We may assume without loss of generality that the right-handed neutrino mass matrix is diagonal and real. As far as the light neutrino masses, which are generated radiatively, are concerned, the last additional interaction term in Eq. (18) has no influence. So the neutrino phenomenology is the same as in the original model. The most general form of the $Z_2 \times Z_2'$-invariant scalar potential can be written as

$$V = m_1^2 H_1^\dagger H + m_2^2 \eta^\dagger \eta + \frac{1}{2} m_3^2 \phi^2$$
$$+ \frac{1}{2} \lambda_1 (H_1^\dagger H)^2 + \frac{1}{2} \lambda_2 (\eta^\dagger \eta)^2 + \lambda_3 (H_1^\dagger H) (\eta^\dagger \eta) + \lambda_4 (H_1^\dagger \eta) (\eta^\dagger H)$$
$$+ \frac{1}{2} \lambda_5 [(H_1^\dagger \eta)^2 + \text{h.c.}] + \frac{1}{4!} \lambda_6 \phi^4 + \frac{1}{2} \lambda_7 (H_1^\dagger H) \phi^2 + \frac{1}{2} \lambda_8 (\eta^\dagger \eta) \phi^2 , \quad (20)$$

from which we obtain the masses of the inert Higgs fields:

$$m_{\eta^\pm}^2 = m_2^2 + \lambda_3 v^2 / 2 \quad (21)$$
$$m_{\eta_R^0}^2 = m_2^2 + (\lambda_3 + \lambda_4 + \lambda_5) v^2 / 2 = m_2^2 + \lambda_L v^2 / 2 \quad (22)$$
$$m_{\eta_L^0}^2 = m_2^2 + (\lambda_3 + \lambda_4 - \lambda_5) v^2 / 2 , \quad (23)$$
$$m_{\phi}^2 = m_3^2 + \lambda_7 v^2 / 2 . \quad (24)$$

Here, $\langle H \rangle = v / \sqrt{2}$ is the Higgs VEV, and $\eta^0 = (\eta_R^0 + i \eta_L^0) / \sqrt{2}$. At this stage, we have assumed that

$$\langle H \rangle = v / \sqrt{2} , \langle \eta \rangle = \langle \phi \rangle = 0 , \quad (25)$$

correspond to the absolute minimum. (The sufficient condition for the absolute minimum of Eq. (20) is given below.) As we can see from Table III, the cold DM candidates are $N_k^c, \eta_R^0, \eta_L^0, \chi$ and $\phi$, where $\eta_R^0$ as dark matter in the original model has been discussed in detail in Refs. [41–43]. To proceed, we assume that the mass relations

$$M_k >> m_{\eta^\pm}, m_{\eta_R^0} > m_{\eta_L^0} > m_\phi, m_\chi \text{ and } m_{\eta_R^0} < m_\phi + m_\chi \quad (26)$$

are satisfied.\(^4\) These relations are chosen because we would like to meet the following requirements:

1. $\mu \rightarrow e \gamma$

The constraint coming from $\mu \rightarrow e \gamma$ is given by [54]

$$B(\mu \rightarrow e \gamma) = \frac{3\alpha}{64\pi (G_F m_{\eta_R^0}^2)^2} \left| \sum_k Y_{\mu k}^\nu Y_{ek}^\nu F_2 \left( \frac{M_k^2}{m_{\eta_R^0}^2} \right) \right|^2 \lesssim 2.4 \times 10^{-12} , \quad (27)$$
$$F_2(x) = \frac{1}{6(1 - x)^4} (1 - 6x + 3x^2 + 2x^3 - 6x^2 \ln x) ,$$

\(^3\) A similar model is considered in Ref. [12].

\(^4\) The possibility $m_{\eta_R^0} < m_{\eta_L^0}$ does not give any new feature of the model.
where the upper bound is taken from Ref. 55. A similar, but slightly weaker bound for \( \tau \to \mu (e) \gamma \) given in Ref. 55 has to be satisfied, too. Since \( F_2(x) \sim 1/3x \) for \( x >> 1 \), while \( 1/12 < F_2(x) < 1/6 \) for \( 0 < x < 1 \), the constraint can be readily satisfied if \( M_k << m_{\eta^\pm} \) or \( M_k >> m_{\eta^\pm} \).

2. \( g_\mu - 2 \)

The extra contribution to the anomalous magnetic moment of the muon, \( a_\mu = (g_\mu - 2)/2 \), is given by 54

\[
\delta a_\mu = \frac{m_\mu^2}{16\pi^2m_{\eta^\pm}^2} \sum_k Y_{\mu k}^\nu Y_{\nu k}^\mu F_2 \left( \frac{M_k^2}{m_{\eta^\pm}^2} \right).
\]

If we assume that \( |\sum_k Y_{\mu k}^\nu Y_{\nu k}^\mu F_2 \left( \frac{M_k^2}{m_{\eta^\pm}^2} \right)| \simeq |\sum_k Y_{\mu k}^\nu Y_{\nu k}^\mu F_2 \left( \frac{M_k^2}{m_{\eta^\pm}^2} \right)| \), then we obtain

\[
|\delta a_\mu| \simeq 2.2 \times 10^{-5} B(\mu \to e\gamma) \lesssim 3.4 \times 10^{-11}
\]

if Eq. (27) is satisfied, where the upper bound is taken from Ref. 55. So, the constraint from \( a_\mu \) has no significant influence.

3. Stable and global minimum

The DM stabilizing symmetry \( Z_2 \) remains unbroken if

\[
\begin{align*}
m_1^2 &< 0, \quad m_2^2 > 0, \quad m_3^2 > 0, \\
\lambda_1, \quad \lambda_2, \quad \lambda_6 > 0, \quad \lambda_3 + \lambda_4 - |\lambda_5|, \quad \lambda_3 > -\frac{1}{2}(\lambda_1 \lambda_2)^{1/2}, \\
\lambda_7 > -\frac{1}{2}(\lambda_1 \lambda_6/3)^{1/2}, \quad \lambda_8 > -\frac{1}{2}(\lambda_2 \lambda_6/3)^{1/2},
\end{align*}
\]

are satisfied. These conditions are sufficient for Eq. (25) to correspond to the absolute minimum. Since \( m_{\eta^\pm_R}^2 - m_{\eta^\pm_L}^2 = \lambda_5 v^2 \), a negative \( \lambda_5 \) is consistent with Eq. (26).

4. Electroweak precision

The electroweak precision measurement requires 41 56

\[
\Delta T \simeq 0.54 \left( \frac{m_{\eta^\pm} - m_{\eta^\pm_R}}{v} \right) \left( \frac{m_{\eta^\pm} - m_{\eta^\pm_L}}{v} \right) = 0.02^{+0.11}_{-0.12},
\]

for \( m_k = 115 – 127 \) GeV. Therefore, \( |m_{\eta^\pm} - m_{\eta^\pm_R}|, \quad |m_{\eta^\pm} - m_{\eta^\pm_L}| \leq 100 \) GeV is sufficient to meet the requirement.

Then, with the assumption of the above mass relations, we look at the radiative neutrino mass matrix 32:

\[
(M_\nu)_{ij} = \sum_k \frac{Y_{i k}^\nu Y_{j k}^\nu M_k}{16\pi^2} \left[ \frac{m_{\eta^\pm_R}^2}{M_k^2 - M_k^2} \ln \left( \frac{m_{\eta^\pm_R}^2}{M_k^2} \right)^2 - \frac{m_{\eta^\pm_L}^2}{M_k^2 - M_k^2} \ln \left( \frac{m_{\eta^\pm_L}^2}{M_k^2} \right)^2 \right]
\]

\[\simeq - \sum_k \frac{Y_{i k}^\nu Y_{j k}^\nu}{16\pi^2} \left[ \frac{m_{\eta^\pm_R}^2}{M_k} \ln \left( \frac{m_{\eta^\pm_R}^2}{M_k} \right)^2 - \frac{m_{\eta^\pm_L}^2}{M_k} \ln \left( \frac{m_{\eta^\pm_L}^2}{M_k} \right)^2 \right] \text{ for } m_{\eta^\pm_R}, m_{\eta^\pm_L} << M_k.
\]
Since $(\mathcal{M}_\nu)_{ij}$ are of order $10^{-1}$ eV and $m_{\eta_R}^2 - m_{\eta_I}^2 = \lambda_5 v^2$, we need $\sum_k Y^\nu_{ik} Y^\nu_{jk} \lesssim O(10^{-9})$ for $|\lambda_5| \gtrsim O(0.1)$. Note, however, that this does not automatically imply that $\sum_{i,k} |Y^\nu_{ik}|^2 \lesssim O(10^{-9})$; and in fact, it could be much larger if we assume a specific flavor structure of $Y^\nu_{jk}$.

If there exists another source for the neutrino mass matrix, we have to add it to Eq. (32).

A. Relic abundance of dark matter

Now we come to the relic abundance of DM. Under the assumption about the mass relations [Eq. (26)], we have to consider the following annihilation processes:\footnote{We neglect the coannihilations, such as that of $\eta_R^0$ with $\eta_I^0$ and $\eta^\pm$ below.}

- $\eta_R^0 \eta_R^0 \leftrightarrow \text{SMs}$,  $\phi \phi \leftrightarrow \text{SMs}$ (Standard annihilation)  
- $\eta_R^0 \eta_R^0 \leftrightarrow \phi \phi$,  $\chi \chi \leftrightarrow \phi \phi$ (Conversion)  
- $\eta_R^0 \chi \leftrightarrow \phi \nu_L$,  $\chi \phi \leftrightarrow \eta_R^0 \nu_L$,  $\phi \eta_R^0 \leftrightarrow \chi \nu_L$ (Semi-annihilation)

We have yet not specified the relative size of $m_\chi$ and $m_\phi$. If $\chi$ is lighter than $\phi$, the conversion of $\chi$ into $\phi$ is kinematically forbidden, and the semi-annihilation in Fig. 6 is the only kinematically allowed annihilation for $\chi$. So, we will consider below only the case $m_\chi > m_\phi$. First, we consider a benchmark set of the input parameter values:

\begin{align*}
m_{\eta_R^0} &= 200 \text{ GeV} \ , \ m_\chi = 190 \text{ GeV} \ , \ m_\phi = 180 \text{ GeV} \ , \\
m_{\eta_I^\pm} &= m_{\eta_R^0} = 210 \text{ GeV} \ , \\
m_h &= 125 \text{ GeV} \ , \ M_1 = M_2 = M_3 = 1000 \text{ GeV} \ , \\
\lambda_3 &= -0.065 \ , \ \lambda_7 = 0.1 \ , \ \lambda_8 = 0.1 \ , \ \lambda_L = -0.2 \ , \\
\sum_{k=1}^{3} |Y^\chi_{ik}|^2 &= 3(0.7)^2 \ , \ \sum_{i,k=1}^{3} |Y^\nu_{ik}|^2 = 9(0.01)^2 .
\end{align*}

FIG. 6: Semi-annihilation diagram (left) and conversion (right).
FIG. 7: $Y^X$ dependence of the relic abundances, $\Omega_T h^2$ (dashed curve), $\Omega_\chi h^2$ (black curve), $\Omega_{\phi} h^2$ (blue (light gray) curve), $\Omega_{\sigma} h^2$ (red (gray) curve), where $Y^X$ controls the size of the semi-annihilation and conversion shown in Fig. 6. The input parameter values are given in Eq. (36).

With this choice of the parameter values, we obtain

$$
< \sigma(\eta_R^0; \text{SMs}) > = 45.66 - 38.21/x , \quad < \sigma(\phi; \text{SMs}) > = 5.93 - 1.92/x , \\
< \sigma(\eta_R^0; \phi) > = 0.46 + 0.29/x , \quad < \sigma(\chi; \phi) > = 0 + 77.18/x , \\
< \sigma(\chi\eta_R^0; \phi \nu_L) > = 0.02 + 0.01/x , \quad < \sigma(\eta_R^0; \chi \nu_L) > = 0.07 + 0.02/x , \\
< \sigma(\chi; \phi) > = 0.07 + 0.04/x ,
$$

in units of $10^{-9}$ GeV$^{-2}$, and

$$
\Omega_T h^2 = 0.1094 , \quad \Omega_\eta h^2 = 0.0062 , \quad \Omega_\chi h^2 = 0.0511 , \quad \Omega_{\phi} h^2 = 0.0521 ,
$$

where $x = (1/m_\eta_R^0 + 1/m_\chi + 1/m_\phi)^{-1}/T = \mu/T$. As we see from Fig. 6, the size of the semi-annihilation and conversion is controlled by $Y^X_k$. In Fig. 7, we show the $Y^X$ dependence of the individual abundances, where we have varied $\sum_k |Y^X_k|^2$, and $Y^X/\rho_{\text{ref}}$ stands for $(\sum_k |Y^X_k|^2/3)(0.1)^{1/2}$. If $Y^X/\rho_{\text{ref}} << 1$, the conversion of $\chi$ and the semi-annihilations $\chi \phi \rightarrow \eta_R^0 \nu_L , \chi \eta_R^0 \rightarrow \phi \nu_L$ become small, such that $\Omega_\chi h^2$ in particular increases.

**B. Imposing constraints**

To be more realistic, we have to impose constraints from direct detection, collider experiments, and perturbativity, $|\lambda_i|, |Y_{ij}^0|, |Y_{ij}^1| < 1$, in addition to Eqs. (27)- (31), which we shall do next. The DM particles $\phi$ and $\eta_R^0$ have tree-level interactions to the quarks, which are shown in Fig. 8. In the following discussions, we ignore the one-loop contributions such

$^6$ Direct detection of two DM particles has been discussed, for instance, in Refs. [18, 19, 22]. LHC signals of $\eta$ dark matter have been discussed in Refs. [41, 57, 58]. See also Refs. [12, 13].
FIG. 8: Tree (left) and one-loop (right) level interactions with the quarks.

as the right diagram in Fig. 8. The spin-independent elastic cross section off the nucleon $\sigma(\phi(\eta_R^0))$ is given by \[\sigma(\phi(\eta_R^0)) = \frac{1}{4\pi} \left( \frac{\lambda L \hat{f} m_N}{m_{\phi(\eta_R^0)} m_h^2} \right)^2 \left( \frac{m_N m_{\phi(\eta_R^0)}}{m_N + m_{\phi(\eta_R^0)}} \right)^2 , \tag{39}\]

where $m_N$ is the nucleon mass, and $\hat{f} \sim 0.3$ stems from the nucleonic matrix element \[51\].

The cross sections have to satisfy \[(\frac{\sigma(\phi)}{\sigma_{UB}(m_\phi)}) \left( \frac{\Omega_\phi h^2}{0.112} \right) + (\frac{\sigma(\eta_R^0)}{\sigma_{UB}(m_{\eta_R^0})}) \left( \frac{\Omega_{\eta_R^0} h^2}{0.112} \right) \lesssim 1 , \tag{40}\]

where $\sigma_{UB}(m)$ is the current experimental limit on the cross section for the DM mass $m$.

In the absence of $\chi$ and $\phi$, the lower-mass region $60 \text{ GeV} \lesssim m_{\eta_R^0} \lesssim 80 \text{ GeV}$ is consistent with all the experimental constraints \[43, 57\]. But the elastic cross section $\sigma(\eta_R^0) \simeq 7.9 \times 10^{-45}(\lambda_L/0.05)^2(60 \text{ GeV}/m_{\eta_R^0})^2 \text{ cm}^2$ with $\lambda_L \gtrsim 0.05$ in this mass range may exceed the upper bound of the XENON100 result \[63\] $7.0 \times 10^{-45} \text{ cm}^2$ for the DM mass 50 GeV at 90% C.L. The higher-mass region, i.e., $m_{\eta_R^0} \gtrsim 500 \text{ GeV}$ with $\sigma(\eta_R^0) \simeq 4.6 \times 10^{-46}(\lambda_L/0.1)^2(500 \text{ GeV}/m_{\eta_R^0})^2 \text{ cm}^2$, will be significant for next-generation experiments such as SuperCDMS \[70\], XENON1T \[71\] or XMASS \[72\].

The presence of $\chi$ and $\phi$ changes the situation. Firstly, the separation of two allowed regions of $m_{\eta_R^0}$ disappears: As far as the relic abundance is concerned, $m_{\eta_R^0}$ is allowed between 80 and 500 GeV too, as we have seen, because $\chi$ and $\phi$ also contribute to the relic abundance. Secondly, the parameter space becomes considerably larger. To see how the allowed parameter space of the model without $\chi$ and $\phi$ changes, we consider a set of $(\delta_1 = m_{\eta^\pm} - m_{\eta_R^0}, \delta_2 = m_{\eta_R^0} - m_{\eta_R^0})$, for which the allowed parameter space without $\chi$

---

\[7\] There exist also one-loop corrections to $\eta_R^0 \to \eta_R^0 q$ \[50\]. See also Ref. \[60\].

\[8\] There exists a marginal possibility to expend slightly this upper bound \[62\].

\[9\] See also \[64\] - \[69\].
FIG. 9: The allowed regime in the $\lambda_L(\lambda_7) - m_{\eta_R}$ plane for $(\delta_1 = 10, \delta_2 = 10)$ GeV with $m_\chi = m_{\eta_R} - 10$ GeV, $m_\phi = m_{\eta_R} - 20$ GeV and $M_k = 1000$ GeV. The green (light gray) and red (dark gray) points are for $\lambda_L$ and $\lambda_7$, respectively.

and $\phi$ is very small. For $(\delta_1 = 10, \delta_2 = 10)$ GeV, for instance, there is no allowed range of $m_{\eta_R} \lesssim 500$ GeV [43]; the low-mass range of $m_{\eta_R}$, for which the relic abundance $\Omega_{\eta}h^2$ is consistent, does not satisfy the LEP constraint. Below we show how this situation changes in the presence of $\chi$ and $\phi$. The LEP constraint implies that the region satisfying $m_{\eta_R} \lesssim 80$ GeV and $m_{\eta} \lesssim 100$ GeV with $\delta_2 \gtrsim 8$ GeV is excluded [43]. Therefore, for $(\delta_1 = 10, \delta_2 = 10)$ GeV, we have to consider only $m_{\eta_R} > 80$ GeV. Further, to suppress the parameter space, we assume that $m_\chi = m_{\eta_R} - 10$ GeV, $m_\phi = m_{\eta_R} - 20$ GeV, and $M_k = 1000$ GeV, and we scan $m_{\eta_R}$ from 80 to 500 GeV.

Figure 9 shows the allowed area in the $\lambda_L(\lambda_7) - m_{\eta_R}$ plane, where all the constraints are taken into account. The allowed mass range for $m_{\eta_R}$ is extended as expected. The reason that there are no allowed points around $m_{\eta_R} \simeq 100$ GeV is the following: Since we keep the mass difference fixed, we have $m_\phi = m_{\eta_R} - 20 \simeq 80$ GeV there. This is the threshold regime for the process $\phi\phi \rightarrow W^+W^-$. So, for $m_{\eta_R}$ just below 100 GeV, the annihilation cross section for $\phi$ is small because of small $\lambda_7$ in this range of $m_\phi$, and therefore the relic abundance $\Omega_\phi h^2$ exceeds 0.12. We see that $m_{\eta_R} = 80$ GeV is allowed, on the other hand. This allowed area exists, though $\lambda_7$ is small, because around $m_\phi = 62$ GeV, the $s$-channel annihilation of $\phi$ becomes resonant due to $m_h = 125$ GeV. For $m_{\eta_R}$ just above 100 GeV, the annihilation cross section for $\phi$ is large because the channel to $W^+W^-$ is now open, so that $\Omega_\phi h^2$ cannot supplement the anyhow small $\Omega_{\eta}h^2$.

If we suppress the constraint from the direct detection, we have a prediction on the direct detection. Figure 10 shows the spin-independent cross section off the nucleon versus the DM mass; the green (light gray) does so for the $\eta$ DM, and the violet (dark gray) area for the $\phi$ DM. We see that the the spin-independent cross sections not only are consistent with the current bound of XENON100 [63], but also are within the accessible range of future experiments.
FIG. 10: The spin-independent cross section off the nucleon is plotted as a function of the DM mass. The green (light gray) and violet (dark gray) areas are for $\eta$ and $\phi$ DM's, respectively, where we have used $(\delta_1 = 10, \delta_2 = 10)$ GeV with $m_\chi = m_\eta R - 10$ GeV, $m_\phi = m_\eta R - 20$ GeV and $M_k = 1000$ GeV.

C. Indirect detection

If DM annihilates sufficiently into SM particles, the resulting cosmic rays may be observable. These are indirect signals of DM, and in fact excesses in $e^+$ [73–76] and in $\gamma$ [77–80] have been recently reported. Indirect detection of DM has been studied within the framework of a two-component DM system in Refs. [8, 10, 13–15, 18, 26, 27], and also within the inert Higgs model in Refs. [42, 81–83]. As we see from the semi-annihilation diagram in Fig. 6, the process produces only a left-handed neutrino as the SM particle. Therefore, we are particularly interested in the neutrinos from the annihilation of captured DM in the Sun [44–53] (see Refs. [4, 5] for a review, and Refs. [83, 84] for the case of the inert Higgs model), because (i) the semi-annihilation produces a monochromatic neutrino ($E_\nu \simeq m_\eta R + m_\phi - m_\chi$, for instance) in addition to those with $E_\nu \simeq m_\eta R$ along with the continuum spectrum, (ii) these neutrinos can be observed at neutrino telescopes [85–87], and (iii) the evolution equations of the DM numbers in the Sun, which describe approaching equilibrium between the capture and annihilation (including conversion and semi-annihilation) rates of DM, are coupled now.

We denote the number of DM particles $\eta, \chi$ and $\phi$ in the Sun by $N_i$, with $i = \eta, \chi$ and $\phi$, respectively. Then the change of $N_i$ with respect to time $t$ is given by

$$\dot{N}_\eta = C_\eta - C_A(\eta \eta \leftrightarrow \text{SM})N_\eta^2 - C_A(\eta \eta \leftrightarrow \phi \phi)N_\eta^2 - C_A(\eta \chi \leftrightarrow \phi \nu_L)N_\eta N_\chi - C_A(\eta \phi \leftrightarrow \chi \nu_L)N_\eta N_\phi,$$

$$\dot{N}_\chi = C_\chi - C_A(\chi \chi \leftrightarrow \phi \phi)N_\chi^2 - C_A(\eta \chi \leftrightarrow \phi \nu_L)N_\eta N_\chi + C_A(\eta \phi \leftrightarrow \chi \nu_L)N_\eta N_\phi - C_A(\phi \chi \leftrightarrow \eta \nu_L)N_\phi N_\chi,$$

$$\dot{N}_\phi = C_\phi - C_A(\phi \phi \leftrightarrow \text{SM})N_\phi^2 + C_A(\eta \eta \leftrightarrow \phi \phi)N_\eta^2 + C_A(\chi \chi \leftrightarrow \phi \phi)N_\chi^2 + C_A(\eta \chi \leftrightarrow \phi \nu_L)N_\eta N_\chi - C_A(\phi \phi \leftrightarrow \eta \nu_L)N_\phi N_\chi,$$

(41) (42) (43)
where the $C_i$’s are the capture rates in the Sun, and the $C_A$’s are proportional to the annihilation cross sections times the relative DM velocity per volume in the limit $v \to 0$:

$$C_{\phi(\eta)} \simeq 1.4 \times 10^{20} f(m_{\phi(\eta)}) \left( \frac{\hat{\sigma}}{0.3} \right)^2 \left( \frac{\lambda_7(L)}{0.1} \right)^2 \left[ \frac{m_h}{125 \text{ GeV}} \right]^{-4} \times \left( \frac{200 \text{ GeV}}{m_{\phi(\eta)}} \right)^2 \left( \frac{\Omega_{\phi(\eta)}h^2}{0.122} \right) \text{s}^{-1}, \ C_{\chi} = 0 ,$$

(44)

where the function $f(m_{\phi(\eta)})$ depends on the form factor of the nucleus, elemental abundance, kinematic suppression of the capture rate, etc., varying from $O(1)$ to $O(0.01)$ depending on the DM mass [50, 51]. The annihilation rates, $C_A$, can be calculated from

$$C_A(ij \leftrightarrow \bullet) = \frac{< \sigma(ij; \bullet) v >}{V_{ij}}, \ V_{ij} = 5.7 \times 10^{27} \left( \frac{100 \text{ GeV}}{\mu_{ij}} \right)^{3/2} \text{cm}^3,$$

(45)

with $\mu_{ij} = 2m_i m_j / (m_i + m_j)$ in the limit $v \to 0$.

There are fixed points of the evolution equations which correspond to equilibrium. Since at the time of the sun’s birth the numbers $N_i$ were zero, the $N_i$’s increase with time and approach the fixed-point values, i.e., equilibrium, at which point $N_i$ assumes its maximal value. So, the question is whether the age of the Sun, $t_\odot \simeq 4.5 \times 10^9$ years, is old enough for $N_i(t_\odot)$ to reach equilibrium. We see from the evolution equations that the fixed-point values are roughly proportional to $(C_i/C_A)^{1/2}$, implying that we need large capture rates $C_i$ to obtain large $N_i(t_\odot)$. The annihilation, conversion and semi-annihilation rates at $t = t_\odot$ are given by

$$\Gamma(ij; \bullet) = d_{ij} C_A(ij \leftrightarrow \bullet) N_i(t_\odot) N_j(t_\odot),$$

(46)

where $d_{ii} = 1/2$ and $d_{ij} = 1$ for $i \neq j$. The observation rate of the neutrinos, $\Gamma_{\text{detect}}$, is proportional to $\Gamma(ij; \bullet)$. As a benchmark, we use the same set of the input parameter values as in Eq. (36). In Fig. 11 we show the time evolution $\sigma^{10}$

$$\Gamma(\text{SM}) = C_A(\eta \eta \leftrightarrow \text{SM}) N_\eta^2/2 + C_A(\phi \phi \leftrightarrow \text{SM}) N_\phi^2/2,$$

(47)

$$\Gamma(\nu) = C_A(\eta \phi \leftrightarrow \chi \nu) N_\eta N_\phi + C_A(\eta \chi \leftrightarrow \phi \nu) N_\eta N_\chi + C_A(\chi \phi \leftrightarrow \eta \nu) N_\chi N_\phi,$$

(48)

$$\Gamma(\nu\nu) = C_A(\eta \eta \leftrightarrow \nu \nu) N_\eta^2/2,$$

(49)

scaled to $10^{20}$ s$^{-1}$, as function of $\tau = t/t_\odot$. As we see from Fig. 11, the rates seem to be saturated: $\Gamma(\text{SM})$ is in fact saturated, but $\Gamma(\nu)$ does not reach its fixed-point value of

10 For the monochromatic neutrinos, i.e. $\Gamma(\nu)$, we have added all the semi-annihilations, because for the mass values given in Eq. (36) the neutrino energies are all close to 200 GeV. Moreover, the first term in the r.h.s. of Eq. (15) (which counts neutrinos of $m_{\eta \eta} + m_{\phi} - m_{\chi} = 190$ GeV) is a dominant contribution with about 95%.
0.002 × 10^{20} \text{s}^{-1} at \tau = t/t_\odot = 1. The saturated value of \Gamma(\text{SM}) is 0.28 \times 10^{20} \text{s}^{-1} for the input parameters of Eq. (36), which is consistent with the upper limit of \sim 2.73 \times 10^{21} \text{s}^{-1} for \text{m}_{\text{DM}} = 250 \text{ GeV} of the AMANDA-II / IceCube neutrino telescope [85]. As for the monochromatic neutrinos, we obtain \Gamma(\nu) = 1.1 \times 10^{-3} \times 10^{20} \text{s}^{-1} and \Gamma(\nu\nu) = 1.3 \times 10^{-7} \times 10^{20} \text{s}^{-1}. To estimate the detection rate \Gamma_{\text{detect}}, we use the formula [88]

\begin{equation}
\Gamma_{\text{detect}} = A P(E_\nu) \Gamma_{\text{inc}},
\end{equation}

where \(A\) is the detector area facing the incident beam, \(P(E_\nu)\) is the probability for detection as a function of the neutrino energy \(E_\nu\), and \(\Gamma_{\text{inc}} = \Gamma/4\pi R_\odot^2\) is the incoming neutrino flux — i.e., the number of neutrinos per unit area per second on the Earth (where \(R_\odot\) is the distance to the Sun \(\simeq 1.5 \times 10^8 \text{ km}\)).\textsuperscript{11} The probability \(P(E_\nu)\) may be approximated as the ratio of the effective detector length \(L\) to the mean free path of the neutrinos in the detector. For the neutrinos (anti-neutrinos), one finds \(P(E_{\nu(\bar{\nu})}) \simeq 2.0(1.0) \times 10^{-11}(L/\text{km})(E_{\nu(\bar{\nu})}/\text{GeV})\), arriving at

\begin{equation}
\Gamma_{\text{detect}} \simeq 2.2(1.1) \times 10^{-21} \left(\frac{A}{\text{km}^2}\right) \left(\frac{L}{\text{km}}\right) \left(\frac{E_{\nu(\bar{\nu})}}{\text{GeV}}\right) \left(\frac{\Gamma}{\text{s}^{-1}}\right) \text{ yr}^{-1},
\end{equation}

which implies that, for the input parameters of Eq. (36), 0.05 events of monochromatic neutrinos with \sim 200 \text{ GeV} per year may be detected at IceCube [85], where we have used \(A = 1\text{km}^2\), \(L = 1\text{km}\).

A total of 0.05 events per year may be too small to be realistic. However, we would like to note that we have studied only one point in the whole parameter space. It will be our future program to implement the sophisticated method of Ref. [89] and to survey the whole parameter space. How to observe the monochromatic neutrinos at neutrino telescopes should also be addressed [90]. Finally, we would like to note that if at least one of the fermionic DM particles in a multi-component DM system has odd parity of the discrete lepton number, then a monochromatic left-handed neutrino, which is also odd, can be produced together with this fermionic DM in a semi-annihilation of DM particles.

IV. CONCLUSION

We have considered the conversion and semi-annihilation of DM in a multi-component DM system. We have found in fictive models that these non-standard DM annihilation processes can influence the relic abundance of DM a lot, which has been recently found for two-component DM systems in Refs. [17, 22, 23].

As a concrete three-component DM system, we have considered a radiative seesaw model of Ref. [32], which is extended to include an extra Majorana fermion \(\chi\) and an extra real

\textsuperscript{11} A sophisticated method to compute the observation rates at IceCube was recently developed in [89].
scalar boson $\phi$. The DM stabilizing symmetry is promoted to $Z_2 \times Z_2'$, and we have assumed that $\eta_R^0$ (the CP-even neutral component of the inert Higgs $SU(2)_L$ doublet), $\chi$ and $\phi$ are DM. We have shown that the previously found separation of the allowed parameter space in the low- and high-mass regions for $\eta_R^0$ disappears in the presence of $\chi$ and $\phi$.

Finally, we have discussed neutrinos coming from the annihilations of the captured DM in the Sun. The evolution equations of the DM numbers in the Sun, which describe approaching equilibrium between the capture and annihilation (including conversion and semi-annihilation) rates of DM, are coupled in a multi-component DM system. Due to the semi-annihilations of DM, monochromatic neutrinos are radiated, and the observation rates of neutrinos have been estimated. Observations of high-energy monochromatic neutrinos from the Sun may indicate a multi-component DM system.
