Measurement of $Z$ boson Production in Pb+Pb Collisions at $\sqrt{s_{NN}} = 2.76$ TeV with the ATLAS Detector

The ATLAS Collaboration

Abstract

The ATLAS experiment has observed 1995 $Z$ boson candidates in data corresponding to 0.15 nb$^{-1}$ of integrated luminosity obtained in the 2011 LHC Pb+Pb run at $\sqrt{s_{NN}}=2.76$ TeV. The $Z$ bosons are reconstructed via di-electron and di-muon decay channels, with a background contamination of less than 3%. Results from the two channels are consistent and are combined. Within the statistical and systematic uncertainties, the per-event $Z$ boson yield is proportional to the number of binary collisions estimated by the Glauber model. The elliptic anisotropy of the azimuthal distribution of the $Z$ boson with respect to the event plane is found to be consistent with zero.

Extensive studies of heavy ion (HI) collisions carried out by the experiments at the Relativistic Heavy Ion Collider (RHIC) at BNL, and the Large Hadron Collider (LHC) at CERN, have established that the hot and dense matter produced in HI collisions causes a significant energy loss on the energetic color-charge carriers propagating through such a medium [1, 2]. An understanding of this phenomenon requires measuring the unmodified production rates of the particles before they lose energy. The best candidates to perform such measurements are particles that do not interact via the strong force. The PHENIX experiment at RHIC measured the properties of photons [3]. At the LHC, the CMS experiment reported results on photons and W bosons [4, 5]. The number of these bosons was found to scale with the number of incoherent nucleon-nucleon collisions. Both the ATLAS and CMS collaborations have reported measurements of $Z \rightarrow \mu\mu$ production at $\sqrt{s_{NN}}=2.76$ TeV [6, 7], which show, within a limited statistical precision, the same scaling behavior. This Letter presents a precise measurement of Z boson production in Pb+Pb collisions at $\sqrt{s_{NN}}=2.76$ TeV, using the di-electron and di-muon decay channels. The Z boson production rate is measured as a function of centrality, rapidity ($y^Z$), transverse momentum ($p_T^Z$), and orientation with respect to the event plane [8].

The ATLAS detector [9] at the LHC covers nearly the entire solid angle around the collision point. It consists of an inner tracking detector surrounded by a thin superconducting solenoid, electromagnetic and hadronic calorimeters, and a muon spectrometer incorporating three superconducting toroid magnet systems.

The inner-detector system (ID) is immersed in a 2 T axial magnetic field and provides charged particle tracking in the range $|\eta| < 2.5$. The high-granularity silicon pixel detector covers the vertex region and is surrounded by the silicon microstrip tracker and the transition radiation tracker.

The calorimeters cover the range $|\eta| < 9.4$. Within the region $|\eta| < 3.2$, electromagnetic calorimetry is provided by barrel and end-cap high-granularity lead liquid-argon (LAr) calorimeters, with an additional thin LAr presampler covering $|\eta| < 1.8$. The electromagnetic calorimeter is backed by a hadronic calorimeter. Forward calorimeters (FCal) are located in the range 3.1 $< |\eta| < 4.9$.

The muon spectrometer (MS) comprises separate trigger and high-precision tracking chambers that measure the deflection of muons in a magnetic field generated by superconducting air-core toroids. The precision chambers cover the region $|\eta| < 2.7$ with three layers of monitored drift tubes (MDT), complemented by cathode strip chambers (CSC) in the innermost layer of the forward region. The muon trigger system covers the range $|\eta| < 2.4$ with resistive plate chambers in the barrel, and thin gap chambers in the end-cap regions.

This analysis uses the 2011 LHC Pb+Pb collision data at $\sqrt{s_{NN}} = 2.76$ TeV, obtained by the ATLAS experiment with integrated luminosity of approximately 0.15 nb$^{-1}$. The data sample for this study was collected using a three-level trigger system [10], which selected events with electron or muon candidates.

Electron candidates were identified at the first trigger level (L1) as a cluster of cells in the electromagnetic calorimeter, formed into $(\Delta \phi \times \Delta \eta) = 0.1 \times 0.1$ trigger towers, within the range $|\eta| < 2.5$, excluding the transition region between calorimeter sections (1.37 $< |\eta| < 1.52$). The cluster transverse energy was required to exceed $E_T = 14$ GeV.

Muon candidates were selected using all three trigger levels. The L1 muon trigger searched for patterns of hits in the trigger chambers consistent with muons. If a muon had $p_T$ exceeding 4 GeV, the event was accepted for further processing by the high-level trigger (HLT). The L1 muon algorithm also identified regions of interest (RoI) within the detector to be investigated by the HLT. In the HLT, the track parameters of each muon were recalculated by including the precision data from the MDT or CSC in the RoI defined by the previous trigger level. Muon candidates were reconstructed either solely from the MS or using combined data from the MS and ID. In addition to the events selected using the RoI-based muon trigger, the reconstruction was performed over the whole MS by the HLT to identify muons with $p_T > 10$ GeV. The full scan searched all events in which a neutral particle
signal was detected in each of two Zero Degree Calorimeters (ZDC) ($|\eta| > 8.3$), or which contained an energy deposition in the calorimeters of $E_T > 10 \text{ GeV}$.

In addition to the single-lepton trigger, each event had to pass the minimum-bias (MB) event selection, which required a timing signal coincidence of better than 3 ns between the MB trigger scintillators ($2.1 < |\eta| < 3.8$), as well as the reconstruction of a collision vertex in the ID. The total number of sampled events is $(1.03 \pm 0.02) \times 10^7$ [11].

Analyzed events are divided into centrality classes. Centrality reflects the overlap volume of the two colliding nuclei. Collisions with a small (large) impact parameter are referred to as central (peripheral). The overlap volume is closely related to the average number of participant nucleons which scatter inelastically in each nuclear collision, $\langle N_{\text{part}} \rangle$, and to the average number of binary collisions between the nucleons of the colliding nuclei, $\langle N_{\text{coll}} \rangle$. Equivalently, $\langle N_{\text{coll}} \rangle$ may be defined as the average nuclear thickness function, $\langle T_{\text{AA}} \rangle$, multiplied by the total inelastic p+p cross section.

The Pb+Pb collision centrality is measured using the scalar sum of transverse energy $\left( \sum E_T \right)$ deposited in the FCAL, calibrated at the electromagnetic energy scale [12]. The fraction of events with more than one Pb+Pb collision is estimated not to exceed 0.05%, except for the most central 5% of events in which the fraction does not exceed 0.5%. A cut on the FCAL energy of $\sum E_T < 3.8 \text{ TeV}$ is applied to prevent contamination by events with multiple Pb+Pb interactions. Glauber model calculations relate centrality to $\langle N_{\text{part}} \rangle$ and $\langle N_{\text{coll}} \rangle$, following the procedure documented in Ref. [13]. In the present sample, $\langle N_{\text{coll}} \rangle$ ($(\langle N_{\text{part}} \rangle)$) ranges from 1683 ± 130 (382 ± 2) for the most central class, 0–5%, to 78 ± 7 (46 ± 3) for the most peripheral class, 40–80%.

The efficiencies of the electron and muon triggers are evaluated from $5.5 \times 10^7$ events selected with the MB trigger during the 2011 run. The MB trigger required a transverse energy deposition of $E_T > 50 \text{ GeV}$ in the calorimeters or a coincidence of both ZDC signals and a track in the ID. The average trigger efficiency for muons with $p_T > 10 \text{ GeV}$ decreases from 98.2 ± 0.5% in peripheral events to 90.9 ± 0.5% in central events, where the ID occupancy is higher. The average trigger efficiency for electrons with $|\eta| < 2.5$ and $E_T > 20 \text{ GeV}$ is 98.1 ± 0.1%, independent of centrality. The trigger efficiency for $Z \rightarrow \mu\mu$ decays ranges from 99.0 ± 0.6% in peripheral events to 95.0 ± 0.9% in central events. For $Z \rightarrow ee$ decays the efficiency is 99.9 ± 0.1% independent of centrality.

For the $Z \rightarrow ee$ analysis, electron candidates are formed using the standard ATLAS reconstruction algorithm [14], requiring the matching of a track to an energy cluster in the electromagnetic calorimeter. Electron selection is limited to $|\eta| < 2.5$ and both electrons are required to have $E_T > 20 \text{ GeV}$. Following the reconstruction requirements, further electron identification cuts are made to reject background. The standard electron identification cuts [14] used in the $p+p$ environment are not suited to the Pb+Pb environment due to the large underlying event (UE) energy deposition in the calorimeter. To address this, a different set of cuts has been developed to accommodate the modification of the calorimeter variables by the presence of the UE. The cuts used are based on the energy balance between the track momentum and cluster energy ($E/p$), as well as calorimeter shower shape variables. Furthermore, the UE energy is estimated (following Ref. [15]) and subtracted on an electron-by-electron basis to recover the proper electron energy.

The electron combined reconstruction and identification efficiency is evaluated in a Monte Carlo simulation using electrons from $7 \times 10^5$ PYTHIA (version 6.425) [10] $p+p \rightarrow Z \rightarrow ee$ events with $66 < m_Z < 116 \text{ GeV}$ and $|y| < 2.5$ embedded into Pb+Pb events generated by the HIJING event generator (version 1.38b) [17]. The response of the ATLAS detector to the generated particles is modeled using GEANT4 [18, 19]. The combined reconstruction and identification efficiency for electrons of $E_T > 20 \text{ GeV}$ ranges from 72% to 76% from central to peripheral events, with a common absolute uncertainty of 5.4%.

For the $Z \rightarrow ee$ analysis, all electrons found in triggered events are paired with each other, requiring that at least one electron in the pair match a trigger object. The opposite-sign charged pairs with an invariant mass satisfying $66 < m_{ee} < 102 \text{ GeV}$ are accepted as signal $Z$ boson candidates. The same-sign pairs in this window are taken as an estimate of the combinatorial background. In total, 772 opposite-sign pairs and 42 same-sign pairs are reconstructed.

In the $Z \rightarrow \mu\mu$ analysis, single muons are reconstructed with several levels of quality [20]. High quality muons are reconstructed in both the MS and ID with consistent angular measurements, as well as with a good match to the event vertex. At least one muon in each pair, matched to the trigger, is required to be of such quality. If the second muon in the pair has hit patterns in the MS and ID satisfying criteria of high reconstruction quality, the minimum $p_T$ threshold is set to 10 GeV for both muons. If the second muon fails this condition, both muons are required to satisfy $p_T > 20 \text{ GeV}$.

The muon combined reconstruction and identification efficiency is evaluated using muons from $5.3 \times 10^5$ PYTHIA $p+p \rightarrow Z \rightarrow \mu\mu$ events with $66 < m_Z < 116 \text{ GeV}$ and $|y| < 2.5$ embedded into HIJING events. For muons with $p_T > 20 \text{ GeV}$, $|\eta| < 2.5$ and associated to the event vertex, the reconstruction efficiency of the MS varies from 97 ± 1% to 98 ± 1% from central to peripheral events. Requiring a match between the MS and ID reduces the efficiency to 89 ± 1% and 91 ± 1%, respectively, due to track loss in the ID, predominantly at $|\eta| > 1.5$. 
As in the $Z \rightarrow ee$ analysis, an invariant mass window of $66 < m_{\mu\mu} < 102$ GeV is used to define oppositely charged muon pairs as $Z$ boson candidates and same-sign charged pairs as a background estimate. In total, 1223 opposite-sign candidates and 14 same-sign pairs are reconstructed in the $Z \rightarrow \mu\mu$ channel.

The invariant mass distributions of the selected pairs together with estimated combinatorial backgrounds are shown in Fig. 1 compared with the simulation normalized to the number of pairs in the region $66 < m_{\ell\ell} < 102$ GeV ($\ell = e, \mu$). In order to calculate the yield, the combinatorial background estimated with the same-sign pairs must be subtracted. Backgrounds from electroweak processes and top pair decays [21] are small compared to the selected acceptance based on the simulation are calculated differentially in event centrality, $p_T^Z$, and $y^Z$. In each decay channel, the correction factor is applied and the background, estimated by the same-sign pairs, is subtracted. The two measurements are averaged with weights set by their respective uncertainties.

The fully corrected $y^Z$ distribution is shown in Fig. 2. No centrality dependence of this shape is observed. The data are compared to a model composed of PYTHIA events normalized to the $Z \rightarrow \ell\ell$ cross section in $p + p$ collisions at $\sqrt{s_{NN}} = 2.76$ TeV taken from next-to-next-to-leading-order (NNLO) calculations used in Ref. [23] and scaled by $\langle T_{AA} \rangle$. Incorporating $p + n$ and $n + n$ collisions would increase the cross section by 3%. The shape is well reproduced by PYTHIA, and the integrated yield is in good agreement with the $\langle T_{AA} \rangle$-scaled NNLO cross section.

The trigger efficiency uncertainties are estimated by using alternative methods and comparing their results with those obtained from the MB data set. For this comparison the simulation trigger efficiency is used, as well as the conditional trigger efficiency of a second lepton in a triggered pair reconstructed as a $Z$ boson.

For each $Z \rightarrow \ell\ell$ analysis, correction factors to account for the efficiency (relative to $Z$ bosons produced with $66 < m_Z < 116$ GeV) and detector resolution within the selected acceptance based on the simulation are calculated differentially in event centrality, $p_T^Z$, and $y^Z$. The trigger efficiency uncertainties are estimated by alternative methods and comparing their results with those obtained from the MB data set. For this comparison the simulation trigger efficiency is used, as well as the conditional trigger efficiency of a second lepton in a triggered pair reconstructed as a $Z$ boson.

As in the $Z \rightarrow ee$ analysis, an invariant mass window of $66 < m_{\mu\mu} < 102$ GeV is used to define oppositely charged muon pairs as $Z$ boson candidates and same-sign charged pairs as a background estimate. In total, 1223 opposite-sign candidates and 14 same-sign pairs are reconstructed in the $Z \rightarrow \mu\mu$ channel.

The invariant mass distributions of the selected pairs together with estimated combinatorial backgrounds are shown in Fig. 1 compared with the simulation normalized to the number of pairs in the region $66 < m_{\ell\ell} < 102$ GeV ($\ell = e, \mu$). In order to calculate the yield, the combinatorial background estimated with the same-sign pairs must be subtracted. Backgrounds from electroweak processes and top pair decays [21] are small compared to the selected acceptance based on the simulation are calculated differentially in event centrality, $p_T^Z$, and $y^Z$. In each decay channel, the correction factor is applied and the background, estimated by the same-sign pairs, is subtracted. The two measurements are averaged with weights set by their respective uncertainties.

The fully corrected $y^Z$ distribution is shown in Fig. 2. No centrality dependence of this shape is observed. The data are compared to a model composed of PYTHIA events normalized to the $Z \rightarrow \ell\ell$ cross section in $p + p$ collisions at $\sqrt{s_{NN}} = 2.76$ TeV taken from next-to-next-to-leading-order (NNLO) calculations used in Ref. [23] and scaled by $\langle T_{AA} \rangle$. Incorporating $p + n$ and $n + n$ collisions would increase the cross section by 3%. The shape is well reproduced by PYTHIA, and the integrated yield is in good agreement with the $\langle T_{AA} \rangle$-scaled NNLO cross section.
the ratio $\langle T_{AA} \rangle$. The ratios are constant within uncertainties for all centrality classes over the range of measured $p_T^Z$.

To further examine the binary collision scaling of the data, the $Z$ boson per-event yields, divided by $\langle N_{coll} \rangle$, are shown in Fig. 4 as a function of $\langle N_{part} \rangle$, in several $p_T^Z$ bins. The figure demonstrates that the $Z \rightarrow ee$ and $Z \rightarrow \mu \mu$ results are consistent within their uncertainties for all $p_T^Z$ and centrality regions. Within the statistical significance of the data sample, the $Z$ boson per-event yield obeys binary collision scaling.

The elliptic anisotropy, $v_2$, of the $Z$ boson is defined as $v_2 = \langle \cos 2(\phi - \Psi_2) \rangle / \sigma_2$, where $\phi$ is the azimuthal angle of the $Z$ boson momentum vector and $\Psi_2$ is the azimuthal angle of the event plane, the plane containing the momentum vectors of both lead nuclei and measured with resolution $\sigma_2$ [24]. The $v_2$ values measured in the two decay channels are consistent and are combined. The main uncertainty on the $v_2$ measurement arises from the event plane (EP) resolution, which is measured from the difference of $\Psi_2$ determined using the two sides of the FCal at positive and negative rapidities [24]. To ensure that the jets associated with $Z$ boson production do not affect the determination of $\Psi_2$, the EP resolution is also measured ordering the FCal sides in the difference according to the direction of the $Z$ boson. A systematic uncertainty of 12 mrad is assigned for possible EP distortion.

The $v_2$ of the $Z$ boson is shown in Fig. 5 as a function of $|y^Z|$, $p_T^Z$, and $\langle N_{part} \rangle$. The averaged $v_2$ of the $Z$ boson has been measured to be $v_2 = -0.015 \pm 0.018 \text{(stat.)} \pm 0.014 \text{(sys.)}$, which indicates an isotropic distribution. This observation is an independent measurement consistent with $Z \rightarrow \ell \ell$ yields being unaffected by the medium in HI collisions.

Using the ATLAS detector, $Z$ boson production has been measured in Pb+Pb collisions at $\sqrt{s_{NN}}=2.76$ TeV.
using 0.15 nb$^{-1}$ of integrated luminosity collected in the 2011 LHC physics run. Within $|y^Z| < 2.5$, and 66 < $m_{\ell\ell} < 102$ GeV, a total of 772 and 1223 Z boson candidates are reconstructed in the $Z \to ee$ and $Z \to \mu\mu$ channels, respectively. The combinatorial background is at the level of 5% in the di-electron channel and 1% for the di-muon channel. The Z boson production yield integrated over $|y^Z| < 2.5$ is consistent between the two channels in all measured $p_T$ and centrality regions. The momentum and rapidity distributions of the Z bosons are consistent with PYTHIA simulations of Z boson production in $p + p$ collisions scaled to the NNLO cross section and multiplied by $(T_{AA})$. Within the uncertainties the Z boson yield is found to be proportional to $(N_{coll})$. The elliptic anisotropy of the Z boson measured as a function of rapidity, $p_T^Z$ and $(N_{part})$ is consistent with zero within the uncertainties of the measurements.

We thank CERN for the very successful operation of the LHC, as well as the support of our institutions without whom ATLAS could not be operated efficiently.

The crucial computing support from all WLCG partners is acknowledged gratefully, in particular from CERN and the ATLAS Tier-1 facilities at TRIUMF (Canada), NDGF (Denmark, Norway, Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy), NL-T1 (Netherlands), PIC (Spain), ASGC (Taiwan), RAL (UK) and BNL (USA) and in the Tier-2 facilities worldwide.

[8] The ATLAS reference system is a Cartesian right-handed coordinate system, with the nominal collision point at the origin. The anticlockwise beam direction defines the positive z-axis, while the positive x-axis is defined as pointing from the collision point to the center of the LHC ring and the positive y-axis points upwards. Transverse quantities, such as $p_T$ and $E_T$, are defined in the $(x,y)$ plane. The azimuthal angle $\phi$ is measured around the beam axis, and the polar angle $\theta$ is measured with respect to the $z$-axis. The rapidity is given by $y = \frac{1}{2} \ln \frac{E_T + p_T}{E_T - p_T}$ and pseudorapidity is defined as $\eta = -\ln \tan(\frac{\theta}{2})$.
