Abstract

The expected sensitivity of Belle is reported for the Dark Photon, A, and Dark Higgs, h′ searches, for mass ranges, respectively of 0.27 < mA < 3 GeV/c² and 0.54 < mW < 10 GeV/c². The Dark Photon and Dark Higgs will be searched for in the Higgs-strahlung channels: e⁺e⁻ → Ah′, with h′ → AA and A → l⁺l⁻ (with l = e or µ). Results will be unblinded soon.

Keywords: Dark Matter, Dark Photon, Dark Higgs, Belle, KEK

1. Introduction

Ordinary matter represents 4 % of the total energy budget of the universe. The remainder is believed to be partitioned as either Dark Energy (73%) or Dark Matter (23%), but the nature of those components is unknown. However, experimental results from direct Dark Matter searches, (e.g. DAMA/LIBRA) [1–4] and other experimental observations that may be interpreted as deviations from the Standard Model (e.g. g-2 [5]), can be explained in the Dark Matter (DM) models by the inclusion of an additional interaction, a dark U(1) interaction [6–16]. This interaction, which is mediated by a dark U(1) boson, also known as the “Dark Photon”, typically has very small couplings to Standard Model particles.

Dark gauge bosons are postulated to have low mass; of order MeV to GeV due to astrophysical constraints [17, 18]. These astrophysical observations include: excesses in the cosmic-ray flux of electrons and/or positrons above expected background beyond normal astrophysical processes and the expected flux of protons and/ or anti-protons. Dark matter could be charged under the dark U(1) symmetry group and then the observed excess might correspond to dark matter annihilating into a Dark Photon A, which in turn decays into l⁺l⁻ (with l = e or µ or possibly τ if energetically allowed).

The ideal tools to discover such particles are therefore not the highest energy hadron collider experiments, but lower-energy lepton high-luminosity collider experiments such as Belle/BelleII and BaBar/SuperB, or dedicated fixed target experiments, several of which are planned or already under construction at JLAB (Newport News, USA) or at MAMI (Mainz, Germany), for example. In Belle, work on dark gauge boson searches was started only recently, and has focused on the strategies proposed by [19–23]. These proceedings will focus on the so-called Higgs-strahlung channel, e⁺e⁻ → Ah′ and in particular the decay mode with 3e⁺3e⁻ and 3µ⁺3µ⁻ final states. The dark U(1) symmetry group could be spontaneously broken, often by a Higgs mechanism, adding a dark Higgs h′ (or dark Higgses) to these models. The dark photon A can decay into either l⁺l⁻, hadrons or invisible particles and h′ into AA, l⁺l⁻, hadrons or invisible particles. The decay mode of the A and h′ depends of the mass difference between A and h′ [21]: (a) mA < mW: h′ → invisible particles, (b) mA < mW < 2mA: h′ → l⁺l⁻ or hadrons, (c) mA > 2mA: h′ → AA. Case (c) will be discussed in this proceedings.

The A and h′ do not necessarily have prompt decays [21, 24]. The decay length of the dark photon is a function of the dark photon coupling strength to Standard Model fermions and is proportional to the inverse of the square of the dark photon coupling. The decay length of the dark Higgs varies for mW > 2mA between being prompt and one meter. In the Higgs-strahlung channel, two couplings are involved: the electromagnetic coupling of the dark photon to the Standard Model fermions, αD; and the dark photon coupling to the dark Higgs, αD. KLOE and BaBar reported their searches on the dark photon and the dark Higgs [25] and [26] (see also contribution of B. Oberhof to these proceed-
ings (27)). KLOE focused their search on \( m_{\ell'} < m_A \) and BaBar on \( m_{\ell'} > 2m_A \) (and with \( A \) and \( h' \) prompt), but no signal was found. Only BaBar could set limits for the highest mass range, \( 0.8 < m_{\ell\ell} < 10.0 \) GeV/c\(^2\) and \( 0.25 < m_A < 3.0 \) GeV/c\(^2\). BaBar looked at two types of final states, fully reconstructed (3\( l^+l^-\)) and partially reconstructed (2\( \mu^+\mu^-X \)) with no signal found. Only BaBar could set limits for the highest mass range, \( 0 < m_{\ell\ell} < 25 \) GeV/c\(^2\), with \( m_{\ell\ell} = 2\pi^+2\pi^-l^+l^- \) where \( l = e, \mu \); and partially reconstructed (2\( \mu^+\mu^-X \)) with \( e^+e^-\mu^+\mu^-X \), where \( X \) denotes any final state other than a pair of pions or leptons. The reason to look for partially reconstructed final states is that above a pair of pions or leptons). The reason to assume \( BF(A \rightarrow e^+e^-) + BF(A \rightarrow \mu^+\mu^-) + BF(A \rightarrow \text{hadrons}) = 1 \) and that \( BF(A \rightarrow \text{hadrons}) = R \), where \( R \) is the hadronic cross section ratio, \( R = \frac{\sigma(e^+e^- \rightarrow \text{hadrons})}{\sigma(e^+e^- \rightarrow l^+l^-)} \). BaBar reported six candidate events: one 4\( \pi \)2\( \pi \), two 4\( \pi \)2\( \mu \), two 4\( \mu \)2\( \pi \) and one 4\( \mu \)X events in a ~ 500 fb\(^{-1}\) data set. There were no candidates in the final states with six leptons. The number of events detected were consistent with background expectations. For low mass range of the dark photon: \( 1 < m_A < 300 \) MeV/c\(^2\), part of the space, coupling strength to Standard Model fermions versus dark photon mass, have been excluded by Beam dump experiments (28–34) by looking at reaction \( pp \rightarrow AX \) for example.

2. Experimental setup

The Belle detector is a large-solid-angle magnetic spectrometer, which consists of a silicon vertex detector (SVD), a central drift chamber (CDD), an array of aerogel threshold Cerenkov counters (ACC), a barrel-like arrangement of time-of-flight scintillation counters (TOF), and an electromagnetic calorimeter (ECL) of CsI(Tl) crystals located inside a super-conducting solenoid that provides a 1.5 T magnetic field. An iron flux-return (KLM) located outside the coil is optimized to detect \( K^0_S \) mesons and to identify muons. A detailed description can be found in [35]. Belle is currently being upgraded to Belle II, an upgraded detector for operation at SuperKEKB, which will have 40 times higher luminosity than KEKB [36]. The KEKB collider [37], located in Tsukuba, Japan, is the world’s highest-luminosity electron-position collider. KEKB has produced more than one \( ab^{-1} \) of data at center-of-mass energies corresponding to the \( \Upsilon(1S) \) to \( \Upsilon(5S) \) resonances, and in the nearby continuum.

3. Particle and reaction identification

The sub-systems used to identify the electrons are primarily the ECL, which measured the energy and the CDC, which measured the momentum [38]. The muons are identified by using the KLM and an analysis combining the measurements of the charged track, and the muon cluster matching [39]. Events with six charged tracks with three pairs of opposite charges are considered for analysis. Furthermore, in order to maintain a high detection efficiency we require that at least three out of the six tracks be identified as leptons.

4. Analysis strategy

Events with six lepton final states from \( e^+e^- \rightarrow Ah' \rightarrow AAA \rightarrow 3l^+3l^- \) \((l = e \text{ or } \mu)\) are reconstructed. Energy and momentum conservation is required. The invariant mass for each combination of leptons is required to be consistent with three distinct \( A \rightarrow l^+l^- \). Combinations with three “equal” masses \((m_{lll}^1, m_{lll}^2 \text{ and } m_{lll}^3) \text{ and } m_{lll} > 2m_{lll}^1\) are kept. The “equality” is defined as follows: \( m_{lll}^\text{mean} - 3\sigma(m_{lll}^\text{mean}) < m_{lll}^1,2,3 < m_{lll}^\text{mean} + 3\sigma(m_{lll}^\text{mean}) \). \( m_{lll}^\text{mean} \) is then calculated. Figure 1 shows the mass difference between the \( m_{lll}^1 \), the highest mass, and \( m_{lll}^3 \) the lowest mass: \( m_{lll}^1 - m_{lll}^3 \) is then calculated. Figure 1 shows the mass difference \( m_{lll}^1 - m_{lll}^3 \) as function of the mass \( m_{lll}^1 \) for the 6 electrons (Figure 1-top) and 6 muons (Figure 1-bottom) final states. For conciseness, the following notations are used: “same sign” for \((l^1l^2l^3)(l^4l^5l^6)\) and “opposite sign” for \((l^1l^2l^3)(l^4l^5l^6)\) (with \( l = e \text{ or } \mu \)). The scatter plot for

5. Background estimation

The background estimation is based on a data driven method. In this method, all combinations that have two pairs where the leptons are combined with their wrong-sign partner and one pair with opposite charge, \((l^1l^2)(l^3l^4)(l^5l^6)\), are kept. The three masses are ordered in decreasing order: \( m_{lll}^1 > m_{lll}^2 > m_{lll}^3 \). The mass difference between the \( m_{lll}^1 \), the highest mass, and \( m_{lll}^3 \) the lowest mass: \( m_{lll}^1 - m_{lll}^3 \) is then calculated. Figure 1 shows the mass difference \( m_{lll}^1 - m_{lll}^3 \) as function of the mass \( m_{lll}^1 \) for the 6 electrons (Figure 1-top) and 6 muons (Figure 1-bottom) final states. For conciseness, the following notations are used: “same sign” for \((l^1l^2l^3)(l^4l^5l^6)\) and “opposite sign” for \((l^1l^2l^3)(l^4l^5l^6)\) (with \( l = e \text{ or } \mu \)). The scatter plot for
the opposite sign: \((e^+e^-)(e^+e^-)(e^+e^-)\) - Figure 1 top-right and \((\mu^+\mu^-)(\mu^+\mu^-)(\mu^+\mu^-)\) - Figure 1 bottom-right have their signal region blinded (red bands), since a blind analysis technique is used and not all selection criteria have been validated. The signal region for the same sign scatter plots \((e^+e^-)(e^+e^-)(e^+e^-)\) - Figure 1 top-left and \((\mu^+\mu^-)(\mu^+\mu^-)(\mu^+\mu^-)\) - Figure 1 bottom-left is unblinded.

The expected background with no constraint on the impact parameter and on the vertex position corresponds to displaced vertex positions up to 80 cm from the interaction point and according to \([21, 24]\) up to \(\epsilon \sim 10^{-6}\). Here, \(\epsilon = \frac{\Delta \rho}{\rho}\) is the strength of the dark photon mixing with the Standard Model hypercharge gauge boson and \(\rho\), the electromagnetic coupling. For the case with a constraint on the impact parameters, the decay length can go up to 6 mm i.e. up to \(\epsilon \sim 10^{-4}\).

Figure 3 left shows a MC simulation test of the background estimation method. The interaction \(e^+e^- \rightarrow 3e^3e^-\) have been generated in phase space. The background estimated from the same sign distribution is consistent with the number of events counted in the signal region of the opposite sign for all \(m_4\) candidates. Figure 3 right shows the expected background deduced from the data same sign analysis.

A statistical method based on the Feldman-Cousins approach \([41]\) is used to then calculate preliminary upper limits (90% CL) for a number of “observed” events equal to the estimated background events for the full luminosity and the prompt case. Figure 4 (left - six electron, right six muons final states) shows the prelimi-
The Dark Photon and the Dark Higgs are searched for in the mass ranges: $0 < m_{h'} \leq 54$ GeV/c$^2$ and $0.30 < m_{h'} < 10.86$ GeV/c$^2$. Based on control data samples, it was found that the background is small, implying that the detection sensitivity scales nearly linearly with integrated luminosity. The expected preliminary Belle sensitivities have been shown. Results for data will be unblinded soon.

7. Conclusions

The Dark Photon and the Dark Higgs are searched for in the mass ranges: $0.27 < m_A < 3$ GeV/c$^2$ and $0.54 < m_{h'} < 10.86$ GeV/c$^2$. Based on control data samples, it was found that the background is small, implying that the detection sensitivity scales nearly linearly with integrated luminosity. The expected preliminary Belle sensitivities have been shown. Results for data will be unblinded soon.
