Prospects for Observing and Localizing Gravitational-Wave Transients with Advanced LIGO, Advanced Virgo and KAGRA

Abbott, B. P. et al. (KAGRA Collaboration, LIGO Scientific Collaboration and Virgo Collaboration)

Received: 22 January 2018 / Accepted: 7 February 2018

Abstract We present possible observing scenarios for the Advanced LIGO, Advanced Virgo and KAGRA gravitational-wave detectors over the next decade, with the intention of providing information to the astronomy community to facilitate planning for multi-messenger astronomy with gravitational waves. We estimate the sensitivity of the network to transient gravitational-wave signals, and study the capability of the network to determine the sky location of the source. We report our findings for gravitational-wave transients, with particular focus on gravitational-wave signals from the inspiral of binary neutron star systems, which are the most promising targets for multi-messenger astronomy. The ability to localize the sources of the detected signals depends on the geographical distribution of the detectors and their relative sensitivity, and 90% credible regions can be as large as thousands of square degrees when only two sensitive detectors are operational. Determining the sky position of a significant fraction of detected signals to areas of 5 deg$^2$ to 20 deg$^2$ requires at least three detectors of sensitivity within a factor of $\sim 2$ of each other and with a broad frequency bandwidth. When all detectors, including KAGRA and the third LIGO detector in India, reach design sensitivity, a significant fraction of gravitational-wave signals will be localized to a few square degrees by gravitational-wave observations alone.

1 Introduction

Advanced LIGO (aLIGO; Harry 2010; Aasi et al. 2015a), Advanced Virgo (AdV; Acernese et al. 2009; Accadia et al. 2012; Acernese et al. 2015) and KAGRA (Somiya 2012; Aso et al. 2013) are kilometer-scale gravitational-wave (GW) detectors that are sensitive to GWs with frequencies of $\sim 20-2000$ Hz.\(^1\) The era of GW astronomy began with the detection of GW150914 (Abbott et al. 2016k), a signal from the coalescence of a binary black hole (BBH); the first confirmed multi-messenger counterpart to a GW observation came with GW170817 (Abbott et al. 2017a), a signal from a binary neutron star (BNS) coalescence which was accompanied by detections across the electromagnetic spectrum (Abbott et al. 2017k). In this article, we describe the currently projected schedule, sensitivity, and sky-localization accuracy for the GW-detector network. We discuss the past and future planned sequence of observing runs (designated O1, O2, O3, etc.) and the prospects for multi-messenger astronomy.

The purpose of this article is to provide information to the astronomy community to assist in the formulation of plans for forthcoming GW observations. In particular, we intend this article to provide the information required for assessing the features of programs for joint observation of GW events using electromagnetic, neutrino, or other facilities (e.g., Abbott et al. 2016i; Adrian-Martinez et al. 2016; Albert et al. 2017c; Abbott et al. 2017c).

The full science of ground-based GW detectors is broad (Abbott et al. 2016), and is not covered in this article. We concentrate solely on candidate GW transient signals. We place particular emphasis on the coalescence of BNS systems, which are the GW source for which electromagnetic follow-up is most promising (Metzger and Berger 2012; Patricelli et al. 2016; Paschalidis 2017; Rosswog et al. 2017; Metzger 2017). However, we also mention BBHs, as they are the most commonly detected source (Abbott et al. 2016d; 2017g). No electromagnetic emission is expected for vacuum BBH mergers (Centrella et al. 2010), but is possible if there is surrounding material (Schnittman 2013), for example remnants of mass lost from the parent star (Perna et al. 2016; Janiuk et al. 2017) or if the binary was embedded in a circumbinary disc or a common envelope (Bartos et al. 2017; Woosley 2016; Stone et al. 2017). For more general introductory articles on GW generation, detection and astrophysics, we point readers to Blanchet (2014); Pitkin et al. (2011); Sathyaprakash and Schutz (2009).

Although our collaborations have amassed a great deal of experience with GW detectors and analysis, it is still difficult to make predictions for both improvements in search methods and for the rate of progress for detectors which are not yet fully installed or operational. The scenarios of detector sensitivity evolution and observing times given here should not be considered as fixed or firm commitments.

As the detectors’ construction and commissioning progress, we intend to release updated versions of this article. This is the third version of the article, written to coincide with the close of the second observing run (O2) of the advanced-detector era. Changes with respect to the previous version (Aasi et al. 2016) are given in Appendix A.

---

\(^1\)LIGO is short for Laser Interferometer Gravitational-wave Observatory. KAGRA is named after the Japanese word for traditional sacred music and dance for the gods kagura; the name has a secondary meaning as an abbreviation for KAmioka GRavitational-wave Antenna. Virgo is not an acronym, and is not written in all caps.
Progress has been made in the commissioning of the detectors. We include projections for KAGRA for the first time; we also include results from the first observing run (O1) and currently available results from O2.

2 Commissioning and observing phases

We divide the development of the GW observatories into three components:

Construction includes the installation and testing of the detectors. This phase ends with acceptance of the detectors. Acceptance means that the interferometers can lock for periods of hours: light is resonant in the arms of the interferometer with no guaranteed GW sensitivity. Construction incorporates several short engineering runs with no astrophysical output as the detectors progress towards acceptance. The aLIGO construction project ended in March 2015. The construction of AdV was completed at the end of 2016. KAGRA will be operational in its full configuration by early 2019.

Commissioning improves the detectors’ performance with the goal of reaching the design sensitivity. Engineering runs in the commissioning phase allow us to understand our detectors and analyses in an observational mode; these are not intended to produce astrophysical results, but that does not preclude the possibility of this happening. Rather than proceeding directly to design sensitivity before making astrophysical observations, commissioning is interleaved with observing runs.

Observing runs begin when the detectors have reached (and can stably maintain) a significantly improved sensitivity compared with previous operation. Observing runs will produce astrophysical results, direct detections from some GW sources and upper limits on the rates or energetics of others. During the first two observing runs (O1 and O2), exchange of GW candidates with partners outside the LIGO Scientific Collaboration (LSC) and the Virgo Collaboration was governed by memoranda of understanding (MOUs; Abadie et al. 2012d; Aasi et al. 2013b). From the start of the third observing run (O3), all GW event candidates identified with high confidence will be released immediately to the full astronomical community. KAGRA will become a part of the global network with full data sharing, once sensitivities comparable with aLIGO and AdV are achieved.

The progress in sensitivity as a function of time will influence the duration of the observing runs that we plan at any stage. Commissioning is a complex process which involves both scheduled improvements to the detectors and tackling unexpected new problems. While our experience makes us cautiously optimistic regarding the schedule for the advanced detectors, we are targeting an order of magnitude improvement in sensitivity relative to the previous generation of detectors over a wider frequency band. Consequently, it is not possible to make concrete predictions for sensitivity or duty cycle as a function of time. We can, however, use our experience as a guide to plausible scenarios for the detector operational states that will allow us to reach the desired

---

2The detection of GW150914 occurred in the engineering run ER8 immediately preceding the formal start of O1.
sensitivity. Unexpected problems could slow down the commissioning, but there is also the possibility that progress may happen faster than predicted here. The schedule of commissioning phases and observation runs will be driven by a cost–benefit analysis of the time required to make significant sensitivity improvements. More information on event rates could also change the schedule and duration of runs.

In Section 2.1 we present the commissioning plans for the aLIGO, AdV and KAGRA detectors. A summary of expected observing runs is in Section 2.2.

2.1 Commissioning and observing roadmap

The anticipated strain sensitivity evolution for aLIGO, AdV and KAGRA is shown in Figure 1. As a standard figure of merit for detector sensitivity, we use the range, the volume- and orientation-averaged distance at which a compact binary coalescence consisting of a particular mass gives a matched filter signal-to-noise ratio (SNR) of 8 in a single detector (Finn and Chernoff 1993). We define $V_z$ as the orientation-averaged spacetime volume surveyed per unit detector time; for a population with a constant comoving source-frame rate density, $V_z$ multiplied by the rate density gives the detection rate of those sources by the particular detector. We define the range $R$ as the distance for which $(4\pi/3)R^3 = V_z$. In Table 1 we present values of $R$ for different detector networks and binary sources. For further insight into the range, and a discussion of additional quantities such as the median and average distances to sources, please see Chen et al (2017). The BNS ranges, assuming two $1.4M_\odot$ neutron stars, for the various stages of the expected evolution are provided in Figure 1, and the BNS and BBH ranges are quoted in Table 1.

Table 1  Plausible target detector sensitivities. The different phases match those in Figure 1. We quote the range, the average distance to which a signal could be detected, for a $1.4M_\odot$+1.4$M_\odot$ binary neutron star (BNS) system and a $30M_\odot$+30$M_\odot$ binary black hole (BBH) system.

There are currently two operational aLIGO detectors (Aasi et al 2015a). The original plan called for three identical 4-km interferometers, two at Hanford (H1 and H2) and one at Livingston (L1). In 2011, the LIGO Lab and IndIGO consortium in India proposed installing one of the aLIGO Hanford detectors (H2) at a new observatory in India (LIGO-India; Iyer et al 2011). In early 2015, LIGO Laboratory placed the H2 interferometer in long-term storage for use in India. The Government of India granted in-principle approval to LIGO-India in February 2016.
Prospects for Observing and Localizing GW Transients with aLIGO, AdV and KAGRA

Fig. 1  Regions of aLIGO (top left), AdV (top right) and KAGRA (bottom) target strain sensitivities as a function of frequency. The binary neutron star (BNS) range, the average distance to which these signals could be detected, is given in megaparsec. Current notions of the progression of sensitivity are given for early, mid and late commissioning phases, as well as the design sensitivity target and the BNS-optimized sensitivity. While both dates and sensitivity curves are subject to change, the overall progression represents our best current estimates.

The first observations with aLIGO have been made. O1 formally began 18 September 2015 and ended 12 January 2016; however, data from the surrounding engineering periods were of sufficient quality to be included in the analysis, and hence the first observations span 12 September 2015 to 19 January 2016. The run involved the H1 and L1 detectors; the detectors were not at full design sensitivity (Abbott et al. 2016g). We aimed for a BNS range of 40 – 80 Mpc for both instruments (see Figure 1), and achieved a 60 – 80 Mpc range. Subsequent observing runs have increasing duration and sensitivity. O2 began 30 November 2016, transitioning from the preceding engineering run which began at the end of October, and ended 25 August 2017. The achieved sensitivity across the run has been typically in the range 60 – 100 Mpc (Abbott et al. 2017g). Several improvements to the aLIGO detectors will be performed between O2 and O3, including further mitigation of technical noises, increase of laser power delivered to the interferometer, and installation of a squeezed vacuum source. Assuming that no unexpected obstacles are encountered, the aLIGO detectors are expected to achieve a 190 Mpc BNS range by 2020. After the first observing runs, it might be desirable to
optimize the detector sensitivity for a specific class of astrophysical signals, such as BNSs. The BNS range may then become 210 Mpc. The sensitivity for each of these stages is shown in Figure 1.

The H2 detector will be installed in India once the LIGO-India Observatory is completed, and will be configured to be identical to the H1 and L1 detectors. We refer to the detector in this state as I1 (rather than H2). Operation at the same level as the H1 and L1 detectors is anticipated for no earlier than 2024.

The AdV interferometer (V1; Accadia et al. 2012) officially joined O2 on 1 August 2017. We aimed for an early step with sensitivity corresponding to a BNS range of 20–65 Mpc; however, AdV is currently using steel wires to suspend the test masses, instead of fused silica fibers. This limits the highest possible BNS range in O2 to 40–60 Mpc; the BNS range achieved to date is 25–30 Mpc. Fused silica fibers will be reinstalled between O2 and O3. Other improvements such as reduction of technical noises, laser power increase and installation of a squeezed vacuum source will also be performed, bringing the AdV BNS range to 65–85 Mpc in 2018–2019. A configuration upgrade at this point will allow the range to increase to approximately 65–115 Mpc in 2020. The design sensitivity, with a BNS range of 125 Mpc, is anticipated circa 2021. The corresponding BNS-optimized range would be 140 Mpc. The sensitivity curves for the various AdV configurations are shown in Figure 1.

The KAGRA detector (K1; Somiya 2012; Aso et al. 2013) is located at the Kamioka underground site. The first operation of a detector in an initial configuration with a simple Michelson interferometer occurred in March 2016 (Akutsu et al. 2018). The detector is now being upgraded to its baseline design configuration. Initial operation at room temperature is expected in 2018. Subsequently, the detector will be cryogenically cooled to reduce thermal noise. Early cryogenic observations may come in 2019–2020 with a range of 8–25 Mpc. Since sensitivity will lag behind that of aLIGO and AdV, observing runs are planned to be short to allow commissioning to proceed as quickly as possible; longer observing runs may begin when the detector nears design sensitivity of 140 Mpc. The exact timing of observations has yet to be decided, but it is currently intended to have a three-month observing run in early 2020, and a six-month run at the start of 2021. The sensitivity curves for the various KAGRA commissioning stages are shown in Figure 1.

GEO 600 (Lück et al. 2010; Dooley et al. 2016) will continue to operate as a GW detector beyond O3 as techniques for improving the sensitivity at high frequency are investigated (Affeldt et al. 2014). At its current sensitivity, it is unlikely to contribute to detections, but with a deliberate focus on high frequency narrow band sensitivity at a few kilohertz, GEO 600 may contribute to the understanding of BNS merger physics, as well as sky localization for such systems, by around 2021. In the meantime, it will continue observing with frequent commissioning and instrument science investigations related to detuned signal recycling and novel applications of squeezed light as well as increasing the circulating power and levels of applied squeezing (Abadie et al. 2011; Grote et al. 2013; Aasi et al. 2013a; Brown et al. 2017).

Finally, further upgrades to the LIGO and Virgo detectors, within their existing facilities (e.g., Hild et al. 2012; Miller et al. 2015; Aasi et al. 2015c) as well as future third-generation observatories, for example, the Einstein Telescope (Punturo et al. 2010; Hild et al. 2011; Sathyaprakash et al. 2012) or Cosmic Explorer (Abbott et al. 2017e), are
envisioned in the future. It is also possible that for some sources, there could be multi-band gravitational-wave observations, where detection with a space-borne detector like the Laser Interferometer Space Antenna (LISA; Amaro-Seoane et al. 2012, 2013) could provide early warning and sky localization (Sesana 2016), as well as additional information on system parameters (Vitale 2016), formation mechanisms (Nishizawa et al. 2016a, b; Breivik et al. 2016) and tests of general relativity (Barausse et al. 2016). These potential future developments are beyond the scope of this paper.

2.2 Past and envisioned observing schedule

Keeping in mind the important caveats about commissioning affecting the scheduling and length of observing runs, the following are plausible scenarios for the operation of the ground-based GW detector network over the next decade:

2015 – 2016 (O1) A four-month run (12 September 2015 – 19 January 2016) with the two-detector H1L1 network at early aLIGO sensitivity (60 – 80 Mpc BNS range). This is now complete.

2016 – 2017 (O2) A nine-month run with H1L1, joined by V1 for the final month. O2 began on 30 November 2016, with AdV joining 1 August 2017 and ended on 25 August 2017. The expected aLIGO range was 80 – 120 Mpc, and the achieved range was in the region of 60 – 100 Mpc; the expected AdV range was 20 – 65 Mpc, and the initial range was 25 – 30 Mpc.

2018 – 2019 (O3) A year-long run with H1L1 at 120 – 170 Mpc and with V1 at 65 – 85 Mpc beginning about a year after the end of O2.

2020+ Three-detector network with H1L1 at full sensitivity of 190 Mpc and V1 at 65 – 115 Mpc, later increasing to design sensitivity of 125 Mpc.

2024+ H1L1V1K1I1 network at full sensitivity (aLIGO at 190 Mpc, AdV at 125 Mpc and KAGRA at 140 Mpc). Including more detectors improves sky localization (Klimenko et al. 2011; Veitch et al. 2012; Nissanke et al. 2013; Rodriguez et al. 2014; Pankow et al. 2018) as well as the fraction of coincident observational time. 2024 is the earliest time we imagine LIGO-India could be operational.

This timeline is summarized in Figure 2; we do not include observing runs with LIGO-India yet, as these are still to be decided. Additionally, GEO 600 will continue observing, with frequent commissioning breaks, during this period. The observational implications of these scenarios are discussed in Section 4.

3 Searches for gravitational-wave transients

Data from GW detectors are searched for many types of possible signals (Abbott et al. 2017). Here we focus on signals from compact binary coalescences (CBCs) and on generic transient or burst signals. CBCs include BNS, neutron star–black hole (NS–BH) and BBH systems.

Observational results of searches for transient signals are reported in (Abbott et al. 2016a, b, 2017a). The O1 results include two clear detections
GW150914 (Abbott et al. 2016k) and GW151226 (Abbott et al. 2016h), and a lower significance candidate LVT151012 (Abbott et al. 2016f,d). All three originate from BBH coalescences (Abbott et al. 2016m,d). No other transient sources have been identified in O1 (Abbott et al. 2016q, 2017c,m). The first results of O2 have been announced: GW170104 (Abbott et al. 2017g), GW170608 (Abbott et al. 2017h) and GW170814 (Abbott et al. 2017i) are from BBH coalescences, and GW170817 (Abbott et al. 2017a) is the first detection of a BNS coalescence.

Using our observation of GW170817, we calculate that the merger rate density has a 90% credible range of $320 - 4740 \, \text{Gpc}^{-3} \, \text{yr}^{-1}$ (Abbott et al. 2017a). This initial estimate assumes that neutron star masses are uniformly distributed between $1 \, M_{\odot}$ and $2 \, M_{\odot}$ and their dimensionless spins are less than 0.4. Compatible estimates for the merger rate were derived from the rate of electromagnetic transients similar to the counterpart of GW170817 (Siebert et al. 2017; Kasliwal et al. 2017; Smartt et al. 2017; Yang et al. 2017; Zhang et al. 2018). Complementary rate estimation based upon astrophysical population models and observations of Galactic BNS systems (e.g., Abadie et al. 2010b; Kim et al. 2013; Dominik et al. 2015; Vangioni et al. 2016; de Mink and Belczynski 2015; Eldridge et al. 2017; Belczynski et al. 2017; Kruckow et al. 2018) remains an active area of research.

While the rates per unit volume of NS–BH and BBH mergers are expected to be lower than for BNSs, the distance to which they can be observed is larger. Consequently, the predicted observable rates are comparable (Abadie et al. 2010b; Rodriguez et al. 2015; Abbott et al. 2016c, Li et al. 2017). From our observations of BBHs, we infer that their rate of mergers is in the range $\sim 1.2 \times 10^{-8} - 2.13 \times 10^{-7} \, \text{Mpc}^{-3} \, \text{yr}^{-1}$ (Abbott et al. 2017g). The non-detection of NS–BHs in O1 allows us to place a 90% upper
limit of the merger rate of $3.6 \times 10^{-6} \text{ Mpc}^{-3} \text{ yr}^{-1}$, assuming $1.4M_\odot + 5M_\odot$ binaries with isotropically distributed spins (Abbott et al. 2016q); the upper limit on the rate decreases for higher mass black holes. Expected detection rates for other transient sources are lower and/or less well constrained.

For the purpose of detection, the gravitational waveform from the inspiral phase of a BNS coalescence is well modeled and matched filtering can be used to search for signals (Lindblom et al. 2008; Buonanno et al. 2009; Brown et al. 2012; Read et al. 2013; Abbott et al. 2016f; Harry et al. 2016). For systems containing black holes, or in which the component spin is significant, uncertainties in the waveform model can reduce the sensitivity of the search (Nitz et al. 2013; Harry et al. 2014; Dal Canton et al. 2015; Taracchini et al. 2014; Pan et al. 2014; Schmidt et al. 2015; Khan et al. 2016; Bustillo et al. 2017).

Searches for bursts make few assumptions on the signal morphology, using time–frequency decompositions to identify statistically significant excess-power transients in the data. Burst searches generally perform best for short-duration signals ($\lesssim 1$ s), although search development remains an area of active research (e.g., Klimenko et al. 2008; Sutton et al. 2010; Chassande-Mottin et al. 2010; Thrane et al. 2011; Adams et al. 2013; Thrane and Coughlin 2013; Cornish and Littenberg 2015; Thrane et al. 2015; Kanner et al. 2016); their astrophysical targets include core-collapse supernovae, magnetar flares, BBH coalescences, cosmic string cusps, and, possibly, as-yet-unknown systems.

In the era of advanced detectors, we are searching in near real-time for CBC and burst signals for the purpose of rapidly identifying event candidates. A prompt notice of a potential GW transient can enable follow-up observations in the electromagnetic spectrum.

A first follow-up program including low-latency analysis, event candidate selection, position reconstruction and the sending of alerts to several observing partners (optical, X-ray, and radio) was implemented and exercised during the 2009 – 2010 LIGO–Virgo science run (Abadie et al. 2012c,b; Evans et al. 2012). Latencies of less than 1 hour were achieved.

In the present follow-up program, the LSC and Virgo distribute the times and sky localizations using the Gamma-ray Coordinates Network (GCN) system, widely used in the astronomical community for the multiwavelength follow-up of gamma-ray bursts. Messages are sent as machine-readable GCN Notices and as prose GCN Circulars, and astronomers communicate the results of observations using GCN Circulars. A shared infrastructure, including a database of results, allows observing partners to announce, coordinate and visualize the coverage of their observations.

Prior to O1, 74 teams signed MOUs to participate in the electromagnetic follow-up program, and for the first event candidate later confirmed as GW150914, 63 were...
operational and covered the full electromagnetic spectrum (Abbott et al 2016[n]). For the first observations with the advanced detectors, thorough checks were performed before alerts were released, resulting in latencies much greater than 1 hour. We expect this latency to be improved in the future as we gain experience with the instruments, and aim for automatic alerts being sent out with only a few minutes latency; continued checks may lead to retractions of some of these low-latency alerts. In the case of GW150914, 25 teams responded to the GW alert and operated ground- and space-based instruments spanning 19 orders of magnitude in electromagnetic wavelength (Soares-Santos et al 2016; Annis et al 2016; Connaughton et al 2016; Ackermann et al 2016; Savchenko et al 2016; Kasiwal et al 2016; Palliyaguru et al 2016; Hurley et al 2016; Morokuma et al 2016; Copperwheat et al 2016; Lipunov et al 2017[a]; Kawai et al 2017; Smartt et al 2016[b]; Evans et al 2016[c]; Diaz et al 2016; Brocato et al 2017). Analyses of archival data were also performed (Troja et al 2016; Tavani et al 2016). No significant electromagnetic counterpart and no afterglow emission was found in optical, ultraviolet, X-rays, or GeV gamma rays. The weak transient found in Fermi-GBM data 0.4 s after GW150914 (Connaughton et al 2016; Bagoly et al 2016) was not confirmed by other instruments like INTEGRAL SPI-ACS (Savchenko et al 2016), AGILE (Tavani et al 2016) or any other experiments of the InterPlanetary Network (Hurley et al 2016). Models have been proposed to tentatively explain electromagnetic emission from BBHs, but there is no clear favorite as yet (Loeb 2016; Woosley 2016[a]; Perna et al 2016; Janiuk et al 2017; Bartos et al 2017; Stone et al 2017; Li et al 2016[a]; Yamazaki et al 2016[a]; Ryan and MacFadyen 2017[a]; Murase et al 2016[a]; Dai et al 2017[a]; Lyutikov 2016[a]; de Mink and King 2017[a]). There was no significant neutrino emission temporally and spatially coincident with the event, and all detected neutrino candidates are consistent with the background (Adrian-Martinez et al 2016[a]; Gando et al 2016[a]; Aab et al 2016[a]; Abe et al 2016[a]; Agostini et al 2017[a]).

Similar follow-up campaigns have been performed for subsequent BBHs. LVT151012 was only identified in an offline search (Abbott et al 2016[a]), as an online CBC search for BBHs was not running at the time. Nevertheless, some searching of archival data has been done, and no confident electromagnetic counterpart has been found (Racusin et al 2017[a]). GW151226 was identified by a low-latency online search (Abbott et al 2016[a]) and a variety of teams followed up; no electromagnetic counterpart has been reported (Cowperthwaite et al 2016[a]; Smartt et al 2016[a]; Copperwheat et al 2016[a]; Racusin et al 2017[a]; Evans et al 2016[a]; Adriani et al 2016[a]; Palliyaguru et al 2016[a]; Yoshida et al 2017[a]; Serino et al 2017[a]; Brocato et al 2017[a]). No significant neutrino counterpart was found in coincidence with either LVT151012 or GW151226 (Albert et al 2017[a]; Gando et al 2016[a]; Aab et al 2016[a]; Abe et al 2016[a]; Agostini et al 2017[a]). For GW170104 (Abbott et al 2017[a]), a Circular with initial localization was sent in under 7 hours; no confirmed electromagnetic or neutrino counterpart has been reported (Blaher et al 2017[a]; Verrecchia et al 2017[a]; Corsi et al 2017[a]; Stalder et al 2017[a]; Goldstein et al 2017[a]; Goldstein et al 2017[a]; Agostini et al 2017[a]; Savchenko et al 2017[a]; Albert et al 2017[a]). Identification of GW170608 was delayed due to maintenance work being undertaken at Hanford at the time of the event (Abbott et al 2017[a]), but a Circular was still issued within 14 hr. No conclusive counterpart has yet been reported. GW170814 was the first event to be confidently detected by Virgo.
and the inclusion of the third detector significantly improved the localization for this event (Abbott et al. 2017d). A Circular and initial sky localization was issued in under 2 hr. No counterpart has been reported so far (Arcavi et al. 2017b). A lack of counterparts is unsurprising given our current understanding of BBHs.

GW170817 was the first GW transient for which a firm electromagnetic counterpart was discovered (Abbott et al. 2017k). On 2017 August 17 12:41:06 UTC, Fermi-GBM triggered on a short GRB, GRB 170817A (Goldstein et al. 2017a), and a GCN was issued after 14 s. About 6 min later, a GW trigger was identified; the signal was consistent with a BNS coalescence (Abbott et al. 2017a) occurring ~ 1.7 s before GRB 170817A (Abbott et al. 2017), and a GCN was issued at 13:08:16 UTC. A three-detector GW localization was issued within 11 hr of detection. An extensive observing campaign was launched, leading to the discovery of the bright transient AT 2017gfo by the One-Meter, Two-Hemisphere team with the 1-m Swope Telescope (Coulter et al. 2017), and confirmed by other teams within an hour (Soares-Santos et al. 2017b, Valenti et al. 2017b, Arcavi et al. 2017a, Tanvir et al. 2017b, Lipunov et al. 2017b). Subsequent infrared–ultraviolet observations targeted the transient and measured its brightness and spectrum, revealing a red-ward evolution (e.g., Villar et al. 2017, X-ray (Troja et al. 2017), Margutti et al. 2017, Haggard et al. 2017, Ruan et al. 2018, Pooley et al. 2017, D’Avanzo et al. 2018) and radio (Hallinan et al. 2017, Alexander et al. 2017, Mooley et al. 2018) afterglows were discovered at the position of the transient after ~ 9 days and ~ 16 days respectively; these were later joined by observation of the optical afterglow (Lyman et al. 2018, Margutti et al. 2018). Follow-up observations did not reveal any neutrino (Albert et al. 2017b) or high-energy gamma-ray (Abdalla et al. 2017) emission at the position of AT 2017gfo. These multimessenger observations support the hypothesis that GW170817 came from a BNS coalescence, which was the source of the short GRB 170817A (Goldstein et al. 2017a, Savchenko et al. 2017a) and a kilonova powered by the radioactive decay of r-process nuclei produced in the collision (Pian et al. 2017, McCully et al. 2017, Smartt et al. 2017, Chornock et al. 2017, Nicholl et al. 2017, Shappee et al. 2017).

The multimessenger observations for GW170817 allow for different studies ranging from astrophysics to fundamental physics and cosmology. The GW and gamma-ray data show that the BNS coalescence and the short gamma-ray are associated (Abbott et al. 2017f). The time delay of ~ 1.7 s between GW170817 and GRB 170817A places a constraint on the source size and bulk Lorentz factor of the emitting region; furthermore, this delay constrains the difference between the speed of light and the speed of gravity, places new bounds on the violation of Lorentz invariance, and tests the equivalence principle by constraining the Shapiro delay between gravitational and electromagnetic radiation (Abbott et al. 2017f). These results limit the range of potential viable alternative theories of gravity (e.g., Creminelli and Vernizzi 2017, Sakstein and Jain 2017, Ezquiaga and Zumalacárregui 2017, Boran et al. 2018, Baker et al. 2017, Arai and Nishizawa 2017). GWs can be used as standard sirens for cosmological measurements (Schutz 1986). Combining the inferred GW distance with the redshift of the host galaxy NGC 4993, it was possible to infer the Hubble constant (Abbott et al. 2017b); the result is in agreement with the values determined from supernova (Riess et al. 2016) and cosmic microwave background measurements (Ade et al. 2016).
Increased detection confidence, improved sky localization, and identification of host galaxy and redshift are just some of the benefits of joint GW–electromagnetic observations. With this in mind, we focus on two points of particular relevance for follow-up of GW events: the source localization afforded by a GW network as well as the relationship between signal significance, or false alarm rate (FAR), and source localization.

3.1 Detection and false alarm rates

Detection pipelines search the data looking for signal-like features. Candidate triggers flagged by a pipeline are assigned a detection statistic to quantify how signal-like they are. For CBC searches, this involves matching a bank of waveform templates [Sathyaprakash and Dhurandhar 1991; Owen 1996; Owen and Sathyaprakash 1999; Babak et al 2006; Cokelaer 2007; Prix 2007; Harry et al 2009; Ajith et al 2014; Brown et al 2012; Capano et al 2016; Dal Canton and Harry 2017] to the data [Abbott et al 2016f,d]; for burst searches, requirements on waveform morphology are relaxed, but coherence of the signal in multiple detectors is required [Abbott et al 2016f, 2017c]. The detection statistic is used to rank candidates; we assess significance by comparing results with those from an estimated background distribution of noise triggers. It is difficult to theoretically model the behaviour of non-Gaussian noise, and therefore the distribution must be estimated from the data [Abadie et al 2010a; Babak et al 2013; Abadie et al 2012a; Abbott et al 2016f, 2016g, 2017c; Messick et al 2017; Abbott et al 2016f,d, 2017c; Nitz et al 2017]. From the background noise distribution we can map a value of the detection statistic to a FAR, the expected rate of triggers with detection statistics equal to or greater than that value, assuming that the data contain no signals. While each pipeline has its own detection statistic, they all compute a FAR, making it easy to compare results. The FAR, combined with the observation time, may then be used to calculate a p-value, the probability of there being at least one noise trigger with a FAR this small or smaller in the observed time. The p-value is distinct from the probability that a trigger is not a real astrophysical GW signal. The p-value assumes that the data contain no signals, whereas the probability of there being a GW must include the hypothesis that there is an astrophysical signal. To calculate the probability that a trigger is a real signal (or not) requires an extra layer of inference, folding in both our knowledge of the distribution of triggers, assumptions about the signal distribution (such as that sources are uniformly distributed in volume), and knowledge and assumptions about the merger rate per unit volume for a class of sources. A method for doing this is described in [Abbott et al 2016f,d].
duration. When a significant problem with the data is identified or a known instrument-
issue affects the searches’ background, the contaminated data are removed from
the analysis data set. Our experience to date is that this removes a small percentage
of the data; for example, in O1 vetoes removed less than 5% of the coincident data
from the CBC analysis, with a single intermittent instrumental problem accounting for
4.65% of that total (Abbott et al 2016e, d, 2017c, 2018). For low-mass CBC searches,
the waveforms are well modeled, and signal consistency tests reduce the background
significantly (Allen 2005; Cannon et al 2015; Usman et al 2016). For burst sources
which are not well modeled, or which spend only a short time in the detectors’ sensi-
tive band, it is more difficult to distinguish between the signal and a glitch, and so a
reduction of the FAR comes at a higher cost in terms of reduced detection efficiency
(or live-time if more vetoes are used).

Search pipelines are run both online, analysing data as soon as they are available in
order to provide low-latency alerts of interesting triggers, and offline, taking advantage
of improved calibration of the data and additional information regarding data quality.
In Figure 3, we show the offline transient search results for O1.

For CBC, we show the cumulative number of triggers at a given FAR for two
pipelines: PyCBC (Dal Canton et al 2014; Usman et al 2016) and GstLAL (Cannon
et al 2012; Privitera et al 2014; Messick et al 2017). In the ongoing O2 analysis, PyCBC
uses an improved detection statistic (Nitz et al 2017). GW150914, LVT151012 and
GW151226 are visible in both the GstLAL and PyCBC results (Abbott et al 2016f, d)
shown in Figure 3.

For bursts, we show distributions for COHERENT Wave Burst (cWB; Klimenko
et al 2016, 2008), Omicron–LALInferenceBurst (oLIB; Lynch et al 2017) and
BayesWave (Cornish and Littenberg 2015; Littenberg and Cornish 2015). The
cWB analysis is split into two frequency bands, above and below 1024 Hz. The
oLIB search is split into two bins, based upon the quality factor Q of the sine–
Gaussian it uses to model the signal; no triggers were identified by the low-Q search.
BayesWave is run as a follow-up to triggers identified by cWB (Kanner et al 2016),
and hence is not completely independent. GW150914 was identified by all three search

For CBC signals, we conservatively estimate that a network SNR threshold of
\( \rho_c \approx 12 \) is required for a FAR below \( \sim 10^{-2} \) yr\(^{-1}\) in the advanced-detector era (Abadie
et al 2012f, 2016; Aasi et al 2016; Berry et al 2015). A combined SNR of 12 corre-
sponds to a single-detector SNR of 8.5 in each of two detectors, or 7 in each of three detectors
(assuming an orientation and sky location for which the detectors have equal sensi-
tivity). The exact threshold will depend upon data quality in each observing run as well
as the mass of the source; in O1, we found that the threshold SNR was lower, around 10.

---

\( ^6 \)Strain data from probable events in O1 and O2 are publicly available from the LIGO Open Science Center losc.ligo.org (Vallisneri et al 2015). Full data from O1 is also available, and data from other observing runs will be added in the future.
3.2 Localization

Following the detection of a GW transient posterior probability distributions for the position are constructed following a Bayesian framework (Veitch et al 2015; Cornish and Littenberg 2015; Singer and Price 2016; Abbott et al 2016m), with information for the sky localization coming from the time of arrival, plus the phase and amplitude of the GW.

An intuitive understanding of localization can be gained by considering triangulation using the observed time delays between sites (Fairhurst 2009, 2011). The effective single-site timing accuracy is approximately

\[ \sigma_t = \frac{1}{2\pi \rho \sigma_f}, \]

where \( \rho \) is the SNR in the given detector and \( \sigma_f \) is the effective bandwidth of the signal in the detector, typically of order 100 Hz. Thus a typical timing accuracy is on the order of \( 10^{-4} \) s (about 1/100 of the 10 ms light travel time between sites). This sets the localization scale. The simple model of Eq. (1) ignores many other relevant issues such as information from the signal amplitudes and phases across the detector network, uncertainty in the emitted gravitational waveform, instrumental calibration accuracies, and correlation of sky location with other binary parameters (Fairhurst 2009; Vitale and Zanolli 2011; Vitale et al 2012; Nissanke et al 2011; Veitch et al 2012; Nissanke et al 2013; Singer et al 2014; Berry et al 2015; Singer and Price 2016).
While many of these affect the measurement of the time of arrival in individual detectors, such factors are largely common between two similar detectors, so the time difference between the two detectors is relatively uncorrelated with these additional parameters.

The timing-triangulation approach underestimates how well a source can be localized, since it does not include all the relevant information. Its predictions can be improved by introducing the requirement of phase and amplitude consistency between detectors (Grover et al. 2014; Fairhurst 2017): it always performs poorly for a two-detector network, but, with the inclusion of phase coherence, can provide an estimate for the average performance of a three-detector network (Berry et al. 2015).

Source localization using only timing for a two-site network yields an annulus on the sky; see Figure 4. Additional information such as signal amplitude and phase, and precession effects resolve this to only parts of the annulus, but even then sources will only be localized to regions of hundreds to thousands of square degrees (Singer et al. 2014; Berry et al. 2015). An example of a two-detector BNS localization is shown in Figure 5. The posterior probability distribution is primarily distributed along a ring, but this ring is broken, such that there are clear maxima.

For three detectors, the time delays restrict the source to two sky regions which are mirror images with respect to the plane passing through the three sites. It is often possible to eliminate one of these regions by requiring consistent amplitudes in all detectors (Fairhurst 2017). For signals just above the detection threshold, this typically yields regions with areas of several tens to hundreds of square degrees. If there is significant difference in sensitivity between detectors, the source is less well localized and we may be left with the majority of the annulus on the sky determined by the
Fig. 5 Posterior probability density for sky location for an example simulated binary neutron star coalescence observed with a two-detector network. Left: Localization produced by the low-latency BAYESTAR code (Singer et al. 2014, Singer and Price 2016). Right: Localization produced by the higher-latency LALINFERENCE (Veitch et al. 2015) (neglecting spin), which also produces posterior estimates for other parameters. These algorithms are discussed in Section 3.2.1, and agreement between them shows that the low-latency localization is comparable to the one produced by the higher-latency pipelines. The star indicates the true source location. The source is at a distance of 266 Mpc and has a network signal-to-noise ratio of $\rho_c = 13.2$ using a noise curve appropriate for the first aLIGO run (O1, see Section 4.1). The plot is a Mollweide projection in geographic coordinates. Figure reproduced from Berry et al. (2015); further mock sky localizations for the first two observing runs can be found at www.ligo.org/scientists/first2years/ for binary neutron star signals and www.ligo.org/scientists/burst-first2years/ for burst signals.

From Eq. (1), it follows that the linear size of the localization ellipse scales inversely with the SNR of the signal and the frequency bandwidth of the signal in the detector (Berry et al. 2015). For GWs that sweep across the band of the detector, such as CBC signals, the effective bandwidth is $\sim 100$ Hz, determined by the most sensitive frequencies of the detector. Higher mass CBC systems merge at lower frequencies and so have a smaller effective bandwidth. For burst transients, the bandwidth $\sigma_f$ depends on the specific signal. For example, GWs emitted by various processes in core-collapse supernovae are anticipated to have relatively large bandwidths, between 150 – 500 Hz (Dimmelmeier et al. 2008, Ott 2009, Yakunin et al. 2010, Ott et al. 2011), largely independent of detector configuration. By contrast, the sky localization region for narrowband burst signals may consist of multiple disconnected regions and exhibit fringing features; see, for example Klimenko et al. (2011), Abadie et al. (2012c), Essick et al. (2015).

In addition to localizing sources on the sky, for CBC signals it is possible to provide distance estimates, since the waveform amplitude is inversely proportional to the luminosity distance (Veitch et al. 2015, Abbott et al. 2016m). Uncertainty in distance measurement is dominated by the degeneracy with the binary’s inclination, which also determines the signal amplitude (Cutler and Flanagan 1994, Nissanke et al. 2010, Aasi et al. 2013c). The degeneracy could be broken by observing with more non co-aligned detectors (Veitch et al. 2012, Rodriguez et al. 2014), or if precession of the orbital plane is observed (Vecchio 2004, van der Sluys et al. 2008, Vitale et al. 2014), but this is not expected for slowly spinning BNS (Farr et al. 2016). Distance information can further aid the hunt for counterparts, particularly if the the localization
can be used together with galaxy catalogs (Nissanke et al 2013; Hanna et al 2014; Fan et al 2014; Blackburn et al 2015; Singer et al 2016a).

Some GW searches are triggered by electromagnetic observations, and in these cases some localization information is known a priori. For example, in GW searches triggered by gamma-ray bursts (Abadie et al 2012c; Aasi et al 2014c;b; Abbott et al 2017), the triggering space-based telescope provides a localization. The coincident observation of GW170817 (Abbott et al 2017a) and GRB 170817A (Goldstein et al 2017a; Savchenko et al 2017a) confirms that BNS mergers are a progenitor for short gamma-ray bursts (Abbott et al 2017), and therefore that gamma-ray bursts are interesting targets for triggered GW searches. Other possible targets for these externally-triggered GW searches could be electromagnetic or neutrino emission from Galactic core-collapse supernovae. It is therefore of great scientific value to have telescopes capable of observing the high-energy spectrum operating during the advanced-detector era (and beyond). Furthermore, the rapid identification of a GW counterpart to such a trigger could prompt further spectroscopic studies and longer, deeper follow-up in different wavelengths that may not always be done in response to gamma-ray bursts (cf. Abbott et al 2017). This is particularly important for gamma-ray bursts with larger sky localization uncertainties, such as those reported by the Fermi-GBM, which are not followed up as frequently as bursts reported by Swift or Fermi-LAT; in the case of GW170817, the LIGO–Virgo localization was tighter than the localization from Fermi-GBM and INTEGRAL (Abbott et al 2017; Goldstein et al 2017a; Savchenko et al 2017a) and also showed that the source was nearby ($40^{+8}_{-14}$ Mpc; Abbott et al 2017), making it a prime target for further follow-up. All GW data are stored permanently, so that it is possible to perform retroactive analyses at any time.

### 3.2.1 Localization of binary neutron star coalescences

Providing prompt localizations for GW signals helps to maximise the chance that electromagnetic observatories can catch a counterpart. Localizations are produced at several different latencies, with updates coming from more computationally expensive algorithms that refine our understanding of the source.

For CBC signals, rapid localization is performed using BAYESTAR (Singer and Price 2016), a Bayesian parameter-estimation code that computes source location using output from the detection pipeline. It can produce sky localizations (as in Figure 5) with latencies of only a few seconds. A similar approach to low-latency localization has been separately developed by Chen and Holz (2015), which find results consistent with BAYESTAR. BAYESTAR can also provide distance estimates (Singer et al 2016a). These can be easily communicated as an additional component of the sky localization: for each line of sight, the distance posterior probability is approximated as a Gaussian multiplied by the distance squared (Singer et al 2016a). Results from BAYESTAR are shared at low latency for prompt follow-up efforts.

At higher latency, CBC parameter estimation is performed using the stochastic sampling algorithms of LALINFERENCEx (Veitch et al 2015). LALINFERENCEx constructs posterior probability distributions for system parameters, not just location like

---

7A data release of example three-dimension localizations in this format, constructed using results from BAYESTAR and LALINFERENCEx for BNS signals, is available from dcc.ligo.org/P1500071/public/html
BAYESTAR, but also mass, orientation, etc. (Aasi et al 2013c; Abbott et al 2016m), by matching GW templates to the detector strain (Cutler and Flanagan 1994; Jaranowski and Krolak 2012). Computing these waveforms is computationally expensive; this expense increases as the detectors’ low-frequency sensitivity improves and waveforms must be computed down to lower frequencies. The quickest LAL INFERENCE BNS follow-up is computed using waveforms that do not include the full effects of component spins (Singer et al 2014; Berry et al 2015; Abbott et al 2017g), localizations can then be reported with latency of hours to a couple of days. Parameter estimation is then performed using more accurate waveform approximates, those that include fuller effects of spin precession and the effects of tidal distortions of neutron stars (Farr et al 2016; Abbott et al 2017g). Provided that BNSs are slowly spinning (Mandel and O’Shaughnessy 2010), the restrictions on the spins should cause negligible difference between the mid-latency LAL INFERENCE and the high-latency fully spinning LAL INFERENCE localizations (Farr et al 2016). Methods of reducing the computational cost are actively being investigated (e.g., Canizares et al 2013; Purrr 2014; Canizares et al 2015; Smith et al 2016; Vinciguerra et al 2017).

Sky localization results from an astrophysically motivated population of BNS signals, assuming a detection threshold of a SNR of 12, are shown in Figure 6 (Singer et al 2014; Berry et al 2015). Results are quantified using the 90% credible region $CR_{0.9}$, the smallest area enclosing 90% of the total posterior probability, and the searched area $A_s$, the area of the smallest credible region that encompasses the true position (Sidery et al 2014): $CR_{0.9}$ gives the area of the sky that must be covered to expect a 90% chance of including the source location, and $A_s$ gives the area that would be viewed before the true location is found using the given sky localization. Results from both the low-latency BAYESTAR and mid-latency LAL INFERENCE analyses are shown. These are discussed further in Section 4.1 and Section 4.2. The two-detector localizations are slightly poorer in O2 than in O1. This is because although the detectors improve in sensitivity at every frequency, with the assumed noise curves the BNS signal bandwidth is lower in O2 for a given SNR because of enhanced sensitivity at low frequencies (Singer et al 2014). Sky localization improves with the expansion of the detector network (Schutz 2011; Klimenko et al 2011; Veitch et al 2012; Rodriguez et al 2014; Gaebel and Veitch 2017; Pankow et al 2018).

The results in Figure 6 show there is negligible difference between the low-latency BAYESTAR and the LAL INFERENCE analyses if the BNS signal is loud enough to produce a trigger in all detectors. However, when the signal is sub-threshold in one, LAL INFERENCE could give a more precise localization, as it still uses strain data from the non-triggered detector (Singer et al 2014; Singer and Price 2016). In preparation for the start of joint three-detector observations in O2, the online CBC pipelines and BAYESTAR have been enhanced to capture and make use of sub-threshold signals in all detectors. Consequently, there should be negligible difference between the low-latency BAYESTAR and LAL INFERENCE localizations even for events that register weakly in one or more detectors. This was the case for GW170817, where both analyses produced a 90% credible area of $\sim 30 \text{ deg}^2$ (Abbott et al 2017a).

For the BNS signals from the sky-localization studies, the average fractional distance uncertainty, defined as the posterior standard deviation divided by the mean, is $\sim 0.25 – 0.30$ (Berry et al 2015; Farr et al 2016).
Fig. 6 Anticipated binary neutron star sky localization during the first two observing runs (top: O1, see Section 4.1; bottom: O2, see Section 4.2). Detector sensitivities were taken to be in the middle of the early (for aLIGO in O1 and AdV in O2) and mid (for aLIGO in O2) bands of Figure 1. The plots show the cumulative fractions of events with sky-localization areas smaller than the abscissa value. Left: Sky area of 90% credible region CR \(BNS\), the (smallest) area enclosing 90% of the total posterior probability. Right: Searched area \(A^{BNS}\), the area of the smallest credible region containing the true position. Results are shown for the low-latency BAYESTAR (Singer and Price 2016) and higher-latency (neglecting spin) LALINFEERENCE (LI) (Veitch et al 2015) codes. The O2 results are divided into those where two detectors (2-det) are operating in coincidence, and those where three detectors (3-det) are operating: assuming a duty cycle of 70—75% for each instrument, the two-detector network would be operating for 42—44% of the total time and the three-detector network 34—42% of the time. The shaded areas indicate the 68% confidence intervals on the cumulative distributions. A detection threshold of a signal-to-noise ratio of 12 is used and results are taken from (Berry et al 2015; Singer et al 2014).

**LALINFEERENCE** also has the ability to include the effects of the detectors’ calibration uncertainty on parameter estimation (Abbott et al 2016m). Calibration is refined as additional measurements are taken, hence sky localization can improve as uncertainty is reduced. Initial results for GW150914 assumed a calibration uncertainty of 10% for the amplitude of the GW strain and 10 deg for its phase (Abbott et al 2017d). Incorporating this calibration uncertainty into the analysis, the 90% credible area was 610 deg\(^2\) (Abbott et al 2016m). By the end of O1, the calibration uncertainty had been improved, such that the 90% credible area was 230 deg\(^2\) (Abbott et al 2016d). If the detectors were assumed to be perfectly calibrated, such that calibration uncertainty could be ignored, the 90% credible area would be 150 deg\(^2\). Sky localization is particularly sensitive to calibration uncertainty and distance is less
affected. For GW150914, the initial distance estimate was $410^{+160}_{-180}$ Mpc (Abbott et al. 2016m), the estimate at the end of the run was $420^{+150}_{-180}$ Mpc, and the equivalent result without calibration uncertainty was $420^{+140}_{-170}$ Mpc (Abbott et al. 2016d). The effects of calibration uncertainty depend upon the signal’s SNR, bandwidth and position of the source relative to the detectors. For GW151226, LVT151012 and GW170104, there is negligible difference between the sky areas or distances with and without calibration uncertainty using the final calibration uncertainties (Abbott et al. 2016d, 2017g).

3.2.2 Localization of bursts

Sky localizations are also produced for burst triggers and distributed for follow-up. The lowest latency burst sky localizations are produced as part of the CWB detection pipeline (Klimenko et al. 2008, 2016). Sky localizations are produced using a constrained likelihood algorithm that coherently combines data from all the detectors. The CWB sky localizations are calculated with a latency of a few minutes; following detection, further parameter-estimation codes analyze the data.

At higher latency, burst signals are analyzed by LALINFERENCEBURST (LIB), a stochastic sampling algorithm similar to the LALINFERENCE code used to reconstruct CBC signals (Veitch et al. 2015), and BAYESWAVE, a reversible jump Markov-chain Monte Carlo algorithm that models both signals and glitches (Cornish and Littenberg 2015). LIB uses sine–Gaussian waveforms (in place of the CBC templates used by LALINFERENCE), and can produce sky localizations in a few hours. BAYESWAVE uses a variable number of sine–Gaussian wavelets to model a signal and glitches while also fitting for the noise spectrum using BAYESLINES (Littenberg and Cornish 2015); it produces sky localizations with a latency of a few days.

The sky-localization performance of burst algorithms depends upon the type of signal. Studies of burst localization using BAYESWAVE in the first year of the advanced-detector era, and using CWB and LIB in the first two years have been completed in (Becsy et al. 2016) and (Essick et al. 2015), respectively. These assumed sensitivities in the middle of the early band for aLIGO in O1, and in the middle of the mid band for aLIGO and the early band for AdV in O2. Sky localization was quantified by the searched area. For the CWB and LIB pipelines an approximate FAR threshold of $1 \text{ yr}^{-1}$ was used to select events; BAYESWAVE was run as a follow-up to triggers identified by CWB (Kanner et al. 2016), and sky localization was only performed on triggers also detected by BAYESWAVE (and not classified as noise or a glitch). The median localization was shown to be $\sim 100–200 \text{ deg}^2$ for a two-detector network in O1 and $\sim 60–110 \text{ deg}^2$ for a three-detector network in O2, with the localization and relative performance of the algorithms depending upon the waveform morphology. Results for Gaussian, sine–Gaussian, broadband white-noise and BBH waveforms are shown in Figure 7 (for the two-detector O1 network and the three-detector O2 network, cf. Figure 4). The variety of waveform morphologies reflect the range of waveforms that could be detected in a burst search (Abadie et al. 2012c).

A high mass BBH, like GW150914 (Abbott et al. 2016k), could be detected by both burst and CBC analyses. In this case, we expect that the CBC localization, which makes use of the additional information available from constraining signals to match waveform templates, is more accurate than the burst localization (cf. Vitale et al. 2016).
### 4 Observing scenarios

In this section we estimate the sensitivity, possible number of detections, and localization capability for each of the observing runs laid out in Section 2.2. We discuss each future observing run in turn and also summarize the results in Table 3.

In the following, we estimate the expected number of BNS coalescence detections using the inferred 90% credible range for the BNS source rate density, 320–4740 Gpc$^{-3}$ yr$^{-1}$ (Abbott et al 2017a). Given the detectors' noise spectral densities, the $p$ detection threshold can be converted into the (source sky-location and orientation averaged) BNS sensitive detection range $\rho_{\text{BNS}}$ (Abadie et al 2010b [2012b]). From this, the BNS source rate density can be converted into an estimate of the number of expected detected events; this estimate carries the large error on the source rate.
density. Similar estimates may be made for NS–BH binaries using the fact that the NS–BH range is approximately a factor of 1.6 larger than the BNS range though the uncertainty in the NS–BH source rate density is slightly larger (Abadie et al. 2010b). We assume a nominal $\rho_c$ threshold of 12, at which the expected FAR is $\sim 10^{-2}$ yr$^{-1}$. However, such a stringent threshold may not be appropriate for selecting candidate triggers for electromagnetic follow-up. For example, selecting CBC candidates at thresholds corresponding to a higher background rate of 1 yr$^{-1}$ ($100$ yr$^{-1}$) would increase the number of true signals subject to electromagnetic follow-up by about 30% (90%). The area localization for these low-threshold signals is, on average, only fractionally worse than for the high-threshold population – by approximately 20% (60%). The localization of NS–BH signals is expected to be similar to that of BNS signals.

For typical burst sources, the gravitational waveform is not well known. However, the performance of burst searches is largely independent of the detailed waveform morphology (Abadie et al. 2012a; Essick et al. 2015), allowing us to quote an approximate sensitive range determined by the total energy $E_{GW}$ emitted in GWs, the central frequency $f_0$ of the burst, the detector noise spectrum $S(f)$, and the single-detector SNR threshold $\rho_{det}$ (Sutton 2013),

$$R_{burst} \simeq \left[ \frac{G}{2\pi^2c^3} \frac{E_{GW}}{S(f_0)f_0^2\rho_{det}^2} \right]^{1/2}. \quad (2)$$

In this article, we quote ranges using $E_{GW} = 10^{-2} M_\odot c^2$ and $f_0 = 150$ Hz; $E_{GW} = 10^{-2} M_\odot c^2$ is an optimistic value for GW emission from stellar collapse (e.g., Abadie et al. 2012e); the uncertainty in $E_{GW}$ means that the quoted burst ranges are more uncertain than their BNS counterparts. We use a single-detector SNR threshold of 8, corresponding to a typical network SNR of $\sim 12$.

The run durations discussed below are in calendar time. In O1, the H1–L1 network had a duty factor of approximately 43%. Table 2 illustrates how the up time for each detector was impacted by various activities or the environment. The two biggest non-observing categories for each detector are Locking and Environmental. Locking refers to the amount of time spent in bringing the interferometers from an uncontrolled state to their lowest noise configuration (Staley et al. 2014). Environmental effects include earthquakes, wind and the microseism noise arising from ocean storms (Effler et al. 2015; Abbott et al. 2016e). The latter two effects have seasonal variation, with the prevalence of storms being higher during the winter months. L1 has a greater sensitivity to microseism noise and to earthquakes than H1 mainly due to the local geophysical environment (Daw et al. 2004). During O1, L1 lost over twice as much observing time to earthquakes, microseism noise and wind than did H1. While we can expect some improvement in duty factors from operating during non-winter months, we can continue to expect at least a 10% impact on operating time from environmental effects. Adding in maintenance, both planned and unplanned, and time spent in locking we currently expect duty factors of at most 70–75% for each instrument during extended runs. Assuming downtime periods are uncorrelated among detectors, this means that all detectors in a three-detector network will be operating

*This assumes a black hole mass of $5 M_\odot$. 

---

22 KAGRA Collaboration, LIGO Scientific Collaboration and Virgo Collaboration
### Table 2

Percentage of time during the first observing run that the LIGO detectors spent in different operating modes as entered by the on-duty operator. Since several factors may influence detector operation at any given time, there is a certain subjectivity to the assignments. Maintenance includes a planned 4-hour weekly period (∼2.4% of the total). Coincident operation of the detectors occurred ∼43% of the time.

in coincidence approximately 34 – 42% of the time, and at least two detectors will be operating for 78 – 84% of the time. For a four-detector network, three or more detectors will be operational around 65 – 74% of the time, and for a five-detector network, three or more detectors will be operating for 84 – 90% of the time. Our estimates for the expected number of detections and the fraction of sources localized account for these duty cycles. The downtime periods are sometimes correlated between detectors, for example planned maintenance periods are often coordinated, and so these coincidence times may be conservative estimates. The number of detections also account for the uncertainty in the detector sensitive ranges as indicated in Figure 1, but do not include any cosmological evolution of the merger rate.

### 4.1 2015 – 2016 run (O1): aLIGO

This was the first advanced-detector observing run, lasting four months, starting 12 September 2015 and ending 19 January 2016.

The aLIGO sensitivity was expected to be similar to the early band in Figure 1, with a BNS range of 40 – 80 Mpc, and a burst range of 40 – 60 Mpc for $E_{GW} = 10^{-2} M_\odot c^2$. The achieved sensitivity was at the better end of this span, with a BNS range of ∼60 – 80 Mpc.

The O1 BNS search volume was ∼2 × 10^5 Mpc^3 yr, and the dominant source of uncertainty on this value is the calibration of the detectors (Abbott et al 2016q). The search volume is $V_z T$, where $V_z = (4\pi/3)R^3$ is the time-averaged volume surveyed and $T$ is the observing time incorporating the effects of the detectors’ duty cycles. We would therefore expect 0.05 – 1 BNS detections. No BNS detections were made, consistent with these expectations (Abbott et al 2016q).

With the two-detector H1–L1 network any detected events are unlikely to be well localized. A full parameter-estimation study using realistic detector noise and an astrophysically-motivated source catalog has been completed for 2015 – 2016 (Berry et al 2015). This used a noise curve in the middle of the early range shown in Figure 1.

9This study used noise from the sixth science run of initial LIGO, recolored to the expected O1 sensitivity curve. The source catalog, as well as the analysis pipeline, is shared in (Singer et al 2014).
the early curve specified in Barsotti and Fritschel (2012). The distribution of results is shown in Figure 6. In Table 3, we present results calculated using BAYESTAR (Singer and Price 2016) for a population of BNS signals, assuming an SNR threshold of 12; the results agree with those of Berry et al. (2015). The median 90% credible region for is 460 – 530 deg$^2$; the searched area $A_{BNS}^*$ is smaller than 20 deg$^2$ for 14 – 17% of events and smaller than 5 deg$^2$ in 4 – 6%.

Equivalent (but not directly comparable) results for bursts are found in Essick et al. (2015). Specific results depend upon the waveform morphology used, but the median searched area is $\sim 1 – 2$ times larger than for BNS signals; part of this difference is due to the burst study using a less-stringent FAR threshold of $\sim 1$ yr$^{-1}$. The distribution of searched areas for four waveform morphologies are shown in Figure 7.

The localizations of GW150914, GW151226 and LVT151012 exhibit the characteristic broken arc for a two-detector network (Abbott et al. 2016i,d). The 90% credible regions are 230 deg$^2$, 850 deg$^2$ and 1600 deg$^2$ respectively (Abbott et al. 2016d). The sky localization for a CBC signal consistent with the properties of GW150914 is shown in Figure 8. This shows the localization with the two-detector O1 network as well as with other detector network configurations (Gaebel and Veitch 2017).

The poor localization from a two-detector network makes follow-up challenging. The electromagnetic follow-up effort for GW150914 is described in Abbott et al. (2016i,n), and the search for coincident neutrinos is described in Adrian-Martinez et al. (2016); Albert et al. (2017c).

4.2 2016 – 2017 run (O2): aLIGO joined by AdV

This was an approximately nine-month run with three detectors for the second part of the run. The aLIGO performance was expected to be similar to the mid band in Figure 1 with a BNS range of 80 – 120 Mpc, and a burst range of 60 – 75 Mpc for $E_{GW} = 10^{-2} M_\odot c^2$; the achieved BNS range is towards the lower part of this band, around 60 – 100 Mpc (Abbott et al. 2017g). The AdV range was anticipated to be within the early band in Figure 1, approximately 20 – 65 Mpc for BNS and 20 – 40 Mpc for bursts. On 1 August 2017, AdV joined O2 with a BNS range of 25 – 30 Mpc.

The potential improvement in sky localization from the addition of a third detector is illustrated in Figure 8.

Anticipated BNS sky localization for 2016 – 2017 (in addition to 2015 – 2016) was investigated in Singer et al. (2014). This assumed a noise curve which lies in the middle of the mid range in Figure 1 for aLIGO – the mid curve specified in Barsotti and Fritschel (2012) – and the geometric mean of the upper and lower bounds of the mid region in Figure 1 for AdV. The distribution of results is shown in Figure 6. In Table 3, we give results for an astrophysically-motivated BNS population, with an SNR threshold of 12, assuming a three-detector network with each detector having an individual duty cycle of 70 – 75%. The results are calculated using BAYESTAR. The median 90% credible region is 230 – 320 deg$^2$, and 7 – 13% of events are expected to have $\text{CR}_{BNS}^{90\%}$ smaller than 20 deg$^2$. The searched area is smaller than 20 deg$^2$ for 33 – 41% of events and smaller than 5 deg$^2$ for 16 – 21%. The burst study of Essick...
Fig. 8  Sky localization of a signal with parameters consistent with those for GW150914. The lines enclose the 90% credible regions with different detector networks. Dark blue is for the O1 two-detector network; light blue is for the same Hanford–Livingston network at design sensitivity; red is for the three-detector network including Virgo, with all detectors at early sensitivity, similar to what was expected for O2, and black is for the three detector network at design sensitivity. The plot is an orthographic projection with right ascension measured in hours and declination measured in degrees. Results taken from Gaebel and Veitch (2017).

et al (2015) gives approximately equivalent results, producing median searched areas a factor of \( \sim 2–3 \) larger than the BNS results; these results are shown in Figure 7.

GW170104 (Abbott et al. 2017g) and GW170608 (Abbott et al. 2017h) were detected prior to Virgo joining O2. Therefore, like the O1 events, they have large 90% credible areas of 1200 deg\(^2\) and 860 deg\(^2\) respectively. The addition of Virgo made a significant impact for GW170814 (Abbott et al. 2017g) and GW170817 (Abbott et al. 2017a). For GW170814, the initial BAYESTAR 90% credible area is reduced from 1160 deg\(^2\) to 100 deg\(^2\) with the addition of Virgo, and the final LALINFEERENCE three-detector localization is 60 deg\(^2\). For GW170817, the initial BAYESTAR 90% credible area is reduced from 190 deg\(^2\) to 31 deg\(^2\) with the addition of Virgo, and the final LALINFEERENCE three-detector localization is 28 deg\(^2\). The inclusion of the third detector to the network enhances localization whether or not it detects the signal, provided that it could detect the signal, as the observed amplitude constrains the source position. As a result of being observed with a three-detector network, and its high SNR, GW170817 has the best GW localization to date.

GW170817 is the first GW signal to have a confirmed electromagnetic counterpart. The discoveries associated with this detection are highlighted in Section 3. An overview
of the extensive multi-messenger observations accompanying GW170817 is given in [Abbott et al. (2017k)].

This is envisioned to be a year long run with three detectors. The aLIGO and AdV sensitivities will be similar to the late and mid bands of Figure 1 respectively, with BNS ranges of 120 – 170 Mpc and 65 – 85 Mpc, and burst ranges of 75 – 90 Mpc and 40 – 50 Mpc for $E_{GW} = 10^{-2} M_\odot c^2$. This gives an expected update 1 – 50 BNS detections. Both the range and the typical sky localization should increase relative to the 2016 – 2017 run. Table 3 gives BAYESTAR localizations assuming detector sensitivities which are the geometric means of the upper and lower bounds of the relevant bands in Figure 1. The median 90% credible region is 120 – 180 deg$^2$, and 12 – 21% of events are expected to have CR$_{BNS}^{0.9}$ smaller than 20 deg$^2$.

4.4 2020+ runs: aLIGO 190 Mpc, AdV 65 – 125 Mpc

At this point we anticipate extended runs with the detectors at or near design sensitivity. The aLIGO detectors are expected to have a sensitivity curve similar to the design curve of Figure 1. AdV may be operating similarly to the late band, eventually reaching the design sensitivity circa 2021. Potential localization for a GW150914-like BBH signal is shown in Figure 8. The fraction of signals localized to areas of a few square degrees is increased compared to previous runs. This is due to the much larger detector bandwidths, particularly for AdV, as well as the increased sensitivity of the network; see Figure 1.

4.5 2024+ runs: aLIGO (including LIGO-India) 190 Mpc, AdV 125 Mpc, KAGRA 140 Mpc

The five-site network incorporating LIGO-India at design sensitivity would have both improved sensitivity and better localization capabilities. The per-year BNS search volume increases giving an expected 11 – 180 BNS detections annually. The addition of more detector sites leads to good source localization over the whole sky (Schutz 2011; Veitch et al. 2012; Nissanke et al. 2013; Rodriguez et al. 2014). Table 3 gives BAYESTAR localizations for an astrophysical population of BNSs, assuming design sensitivity and a 70 – 75% duty cycle for each detector. The median 90% credible region is 9 – 12 deg$^2$, 65 – 73% of events are expected to have CR$_{BNS}^{0.9}$ smaller than 20 deg$^2$, and the searched area is less than 20 deg$^2$ for 87 – 90%.

5 Conclusions

We have presented possible observing scenarios for the Advanced LIGO, Advanced Virgo and KAGRA network of GW detectors, with emphasis on the expected sensitivities and sky-localization accuracies. This network began operation in September 2015.
Table 3 Summary of a plausible observing schedule, expected sensitivities, and source localization with the Advanced LIGO, Advanced Virgo and KAGRA detectors, which will be strongly dependent on the detectors’ commissioning progress. Ranges reflect the uncertainty in the detector noise spectra shown in Figure 1. The burst ranges assume standard-candle emission of $10^{-2} M_\odot c^2$ in gravitational waves at 150 Hz and scale as $E_\text{gw}^{1/2}$, so it is greater for more energetic sources (such as binary black holes). The BNS localization is characterized by the size of the 90% credible region (CR) and the searched area. These are calculated by running the BAYESTAR rapid sky-localization code (Singer and Price 2016) on a Monte Carlo sample of simulated signals, assuming sensitivity curves in the middle of the plausible ranges (the geometric means of the upper and lower bounds). The variation in the localization reflects both the variation in duty cycle between 70% and 75% as well as Monte Carlo statistical uncertainty. The estimated number of BNS detections uses the actual ranges for 2015 – 2016 and 2017 – 2018, and the expected range otherwise; future runs assume a 70 – 75% duty cycle for each instrument. The BNS detection numbers also account for the uncertainty in the BNS source rate density (Abbott et al 2017a). Estimated BNS detection numbers and localization estimates are computed assuming a signal-to-noise ratio greater than $\sim 12$. Burst localizations are expected to be broadly similar to those derived from timing triangulation, but vary depending on the signal bandwidth; the median burst searched area (with a false alarm rate of $\sim 1 \text{ yr}^{-1}$) may be a factor of $\sim 2 – 3$ larger than the values quoted for BNS signals (Essick et al 2015). No burst detection numbers are given, since the source rates are currently unknown. Localization numbers for 2016 – 2017 include Virgo, and do not take into account that Virgo only joined the observations for the latter part the run. The 2024+ scenario includes LIGO-India at design sensitivity.

The first BBH detection was made promptly after the start of observations in September 2015; they are the most commonly detected GW source, but are not a promising target for multi-messenger observations. GW detections will become more common as the sensitivity of the network improves. The first BNS coalescence was detected in August 2017. This was accompanied by observations across the electromagnetic spectrum (Abbott et al 2017k). Multi-messenger observations of...
BNSs provide new insights into binary evolution, nuclear physics, cosmology and gravitational physics.

Optimizing the multi-messenger follow-up and source identification is an outstanding research topic (e.g., Abadie et al. 2012b, Aasi et al. 2014a, Kasiwal and Nissanke 2014, Singer et al. 2014, Cannon et al. 2012, Evans et al. 2016a, Gehrels et al. 2016, Ghosh et al. 2016, Chan et al. 2017, Rana et al. 2017, Salafia et al. 2017, Patricelli et al. 2018). Triggering of focused searches in GW data by electromagnetically-detected events can also help in recovering otherwise hidden GW signals (Aasi et al. 2014c). Multi-messenger follow-up of GW candidates may help confirm GW candidates that would not be confidently identified from GW observations alone. However, such follow-ups need to deal with large position uncertainties, with areas of many tens to thousands of square degrees. This is likely to remain the situation until late in the decade.

The purpose of this article is to provide information to the astronomy community to facilitate planning for multi-messenger astronomy with advanced GW detectors. While the scenarios described here are our best current projections, they will evolve as detector installation and commissioning progress. We will therefore update this article regularly.

A Changes between versions

Since publication of the previous version (Aasi et al 2016), several updates to the document have been made. The most significant changes are the inclusion of details regarding KAGRA, and results from O1 and O2, including GW170817, the first detection with a unambiguous multi-messenger counterpart (Abbott et al 2017k). The key differences are outlined below.

A.1 Updates to detector commissioning

The plausible detector scenarios remain largely unchanged, but details of O1 and O2 have been updated. Specific updates to the detector scenarios are:

1. The addition of KAGRA to Figure 1 and Figure 2.
2. Table 1 has been added which includes BNS ranges and $30M_\odot + 30M_\odot$ BBH ranges.
3. The O1 sensitivity has been updated following the completion of the run (12 September 2015 – 19 January 2016). We believed that the O1 BNS range would plausibly be 40 – 80 Mpc, and the actual range was 60 – 80 Mpc.
4. The formal transition to O2 was 30 November 2016, and the run ended 25 August 2017. The run is approximately nine calendar months in duration, but includes a two-week break at the end of December and a three-week commissioning break in May. The achieved aLIGO BNS range so far was approximately 60 – 100 Mpc (Abbott et al 2017g).
5. The AdV detector officially joined the O2 run on 1 August 2017. The achieved AdV BNS range was approximately 25 – 30 Mpc.
6. As a consequence of the extended O2 run, the start of O3 is now expected to be in 2018, approximately a year after the end of O2. O3 is now planned to be a year in duration.
7. Figure 2 has been updated to show the current planned timeline.
8. Based on our experience in O1 and O2, we have revised our predicted duty cycles, we believe that single-detector duty cycles of 70% – 75% for extended runs are more realistic than the previous value of 80%.
9. We have updated the final observing scenario, the 2024+ case, to be a five-detector network including KAGRA.
10. Progress has been made towards establishing LIGO-India, with the the Indian government granting in-principle approval; however, it is still too early to give a definite timeline for the observing schedule. 2024 is the earliest we imagine it could be operational.
11. Some of the BNS ranges associated with different observing scenarios have changed as a result of using an updated calculation, including cosmological corrections. For all cosmological calculations, we assume a flat cosmology with Hubble parameter $H_0 = 67.9$ km s$^{-1}$ Mpc$^{-1}$, and density parameters $\Omega_m = 0.3065$ and $\Omega_\Lambda = 0.6935$ (Ade et al 2016). The sensitivity curves themselves have not been modified. Ranges are rounded to the nearest megaparsec below 15 Mpc, rounded
to the nearest 5 Mpc between 15 Mpc and 1000 Mpc, and to the nearest 10 Mpc above 1000 Mpc.

A.2 Updates to data analysis

In addition to the progress made with regards to the detectors, there have also been significant advances from analysing the data. We now include results from O1 (Abbott et al 2016d,q, 2017c) and initial results from O2; these include the first detections of BBH and BNS systems (Abbott et al 2016k,h,d, 2017g,h,i,a). Multi-messenger searches for counterparts to these detections are described in Abbott et al (2016n), Adrian-Martinez et al (2016), Albert et al (2017c), [Abbott et al 2017k]. Specific updates that have been made are:

1. Figure 3 has been updated to include O1 results; the surrounding text has been updated to discuss the detection pipelines used in O1 (Abbott et al 2016f,d,l, 2017c).
2. Results using the BAYESWAVE algorithm (Bécsey et al 2016), appropriate for O1, have been included in Figure 7.
3. Figure 8 shows a sky localization, created using current parameter-estimation techniques, illustrating how localization improves for different network configurations for a GW150914-like signal (Gaebel and Veitch 2017).
4. Table 3 now includes numbers summarising results from O1 and the new 2024+ scenario including KAGRA. Sky localization numbers are now calculated using BAYESTAR (Singer and Price 2016) for all epochs.
5. BNS merger rates have been updated following the observation of GW170817. The post-detection range is 320 – 4740 Gpc$^{-3}$ yr$^{-1}$ (Abbott et al 2017a), consistent with the previous expectation of 10 – 10$^4$ Gpc$^{-3}$ yr$^{-1}$ (Abadie et al 2010b).

We defer describing the full results of O2 until a future update.
