(Dated: October 7, 2013)

The center of the Milkyway is a host to energetic phenomena across many electromagnetic wavebands and now possibly of high-energy neutrinos. We show that 5 out of 21 IceCube shower-like events, including a PeV event, likely originated from the Galactic Center region. Hard spectrum and flux inferred from these events are inconsistent with atmospheric neutrinos. The flux of these neutrinos is consistent with an extrapolation of the gamma-ray flux measured by Fermi-LAT from the inner Galactic region. This indicates a common hadronic origin of both, powered by supernovae. Three other shower-like events are spatially correlated with the Fermi bubbles, originating from the Galactic Center activity, within the uncertainty of reconstructing their arrival directions. Origin of the other neutrino events, including 7 track-like events, is still elusive.

PACS numbers: 95.85.Ry, 98.70.Sa, 14.60.Pq

The IceCube Collaboration has recently announced detection of 26 neutrino events with energies in the $\sim 30$–250 TeV range [1], in addition to the two events announced earlier with $\sim 1$ PeV energy each [2]. Among these 28 contained vertex events, for which electromagnetic energy deposition in the detector from $\nu_l \rightarrow l + X; l = e, \mu, \tau$ interactions can be reliably reconstructed, 21 are shower-like events (including the two PeV events) without visible muon tracks and 7 are muon track-like events. These events, collected over 662 days livetime, constitute a 4.3$\sigma$ signal over an expected background of $10.6^{+4.5}_{-3.9}$ events from the atmospheric neutrino flux models [1]. Although an atmospheric origin of these $\nu$’s cannot be ruled-out completely, this is most likely the first statistically significant signal of high-energy astrophysical neutrinos [3] [4].

Figure 1 shows the arrival directions of the 28 IceCube neutrino events, adapted from the skymap in Ref. [1], in Galactic coordinates. A 15$^\circ$ error circle has been drawn around each of the shower-like events, to reflect the uncertainty in reconstructing the arrival directions of these kind of events [29]. The arrival directions of the track-like events has an uncertainty of the order of a few degree. It is interesting to note that the largest concentration of

\*Electronic address: srazzaque@uj.ac.za
events (5 shower-like) is at or near the Galactic Center, within uncertainties of their reconstructed directions, and an additional 3 shower-like events have their arrival directions consistent with the Fermi bubbles [3]. There is an absence of any track-like events in this region. Most of the track-like events are out of the Galactic plane and at least 4 of them are correlated with shower-like events in those regions.

The IceCube Collaboration has reported [2] the average neutrino effective areas for the shower-like events, over 4π solid angle and at 1 PeV, as $A_e \approx 5 \, \text{m}^2$, $A_\mu \approx 1 \, \text{m}^2$, $A_\tau \approx 2 \, \text{m}^2$, respectively for $\nu_e$, $\nu_\mu$ and $\nu_\tau$ ($\nu$ refers to $\nu + \bar{\nu}$ throughout). For the two events at ≈ 1 PeV each within $t_{\text{live}} = 615.9$ days livetime, the required isotropic diffuse $\nu$-flux at $E = 1 \, \text{PeV}$ is

$$E^2 \Phi(\nu_e + \nu_\mu + \nu_\tau) \approx \frac{1}{4\pi} \left(\frac{2 \times 10^6 \, \text{GeV}}{A_e + A_\mu + A_\tau}\right) t_{\text{live}} \sim 3.7 \times 10^{-8} \, \text{GeV sr}^{-1} \, \text{cm}^{-2} \, \text{s}^{-1},$$

as also calculated in Ref. [2]. However, this flux could be ≈ 20% lower when the effective area for muon track-like events are included [3]. The effective areas are a factor of ≈ 3 smaller at 100 TeV, as can be found by comparing them for the 22 string IceCube configuration [6]. Among the 5 shower-like events which are spatially consistent with the Galactic Center region, 1 event has ≈ 1.1 PeV energy while the rest have energies in the ≈ 30–250 TeV range. Note that the reported energy is electromagnetic-equivalent energy deposited in showers [1]. The actual neutrino energy is higher. Both neutral-current (NC) and charge-current (CC) interactions of neutrinos can produce shower events, the deposited energy in showers, however, is significantly different between these two interaction channels. While for CC the shower energy (for events without visible muon tracks) is almost equivalent to the neutrino energy, for NC the shower energy is ≈ 40%-25% of the neutrino energy in the 10 TeV-10 PeV range [7]. Bearing this uncertainty of neutrino energy reconstruction in mind, we assume a common 100 TeV energy for these 4 events.

Assuming all 5 of these events originated from within a 8° circular region around the Galactic Center (solid angle $\Omega_{GC} = 2\pi (1 - \cos 8°) = 0.06 \, \text{sr}$), given ≈ 15° uncertainty in reconstructing the arrival directions of these events (see Fig. 1), we calculate $\nu$ fluxes at 100 TeV and 1 PeV from this region as

$$E^2 \Phi(\nu_e + \nu_\mu + \nu_\tau) \approx \begin{cases} 1.3 \times 10^{-9} \, \text{GeV cm}^{-2} \, \text{s}^{-1}; \quad (100 \, \text{TeV}) \\ 1.1 \times 10^{-9} \, \text{GeV cm}^{-2} \, \text{s}^{-1}; \quad (1 \, \text{PeV}), \end{cases}$$

following Eq. (1) but with $t_{\text{live}} = 662$ days and by multiplying with $\Omega_{GC}$. This corresponds to a hard, $\Phi \propto E^{-1}$ with $\Gamma \sim 2$, $\nu$-flux from the Galactic Center region. Given the 7 : 1 ratio of the effective areas for the $\nu_e + \nu_\tau : \nu_\mu$ shower-like events, the ratio of the $\nu_e + \nu_\tau : \nu_\mu$ fluxes from the Galactic Center region can be nearly equal and yet no detection of any $\nu_\mu$ events so far. Including the energy-dependent effective area for muon track-like events changes the ratio somewhat but the conclusion about the nearly equal flavor ratio does not change. As for comparisons, the expected conventional atmospheric $\nu$-flux [8] from the Galactic Center region [3] within $\Omega_{GC}$ is

$$E^2 \Phi(\nu_\mu) = 5.0 \times 10^{-11} \, (E/\text{PeV})^{-1.6} \, \text{GeV cm}^{-2} \, \text{s}^{-1},$$

much smaller than the PeV flux in Eq. (2). At 100 TeV the atmospheric $\nu_\mu$ flux is comparable to the flux in Eq. (2). However, note that the atmospheric $\nu_e$ flux is steeper and at least a factor of 10 smaller than the $\nu_\mu$ flux in Eq. (3) in this energy range. Moreover, neutrino oscillation does not produce significant $\nu_e$ flux at these energies. Therefore atmospheric neutrino fluxes are inconsistent with the nearly equal or higher $\nu_e + \nu_\tau : \nu_\mu$ flux ratio expected from the 5 shower-like events detected by IceCube from the Galactic Center region.

Interestingly, the Fermi-LAT measures [9] a 100 GeV $\gamma$-ray flux of $\sim 3.5 \times 10^{-3} \, \text{MeV cm}^{-2} \, \text{s}^{-1} \, \text{sr}^{-1}$ from the inner Galactic region ($|l| < 80°$ and $|b| < 8°$). This flux, within $\Omega_{GC}$, is $\sim 2.1 \times 10^{-7} \, \text{GeV cm}^{-2} \, \text{s}^{-1}$ which is far above the $\nu$-fluxes in Eq. (2). An extrapolation of the Fermi-LAT flux in the 0.1–1 PeV range is highly uncertain, due to non-power-law nature of this flux. Moreover, both $\pi^0$ decay and inverse Compton emissions contribute to this flux at high energies [9]. Extrapolating the $\pi^0$ decay $\gamma$-ray flux of $\sim 10^{-3} \, \text{MeV cm}^{-2} \, \text{s}^{-1} \, \text{sr}^{-1}$ at 100 GeV, with $E^{-2.3}$ spectrum, to 100 TeV and 1 PeV gives a flux of $\sim 7.6 \times 10^{-9} \, \text{GeV cm}^{-2} \, \text{s}^{-1}$ and $\sim 3.8 \times 10^{-9} \, \text{GeV cm}^{-2} \, \text{s}^{-1}$, respectively, within $\Omega_{GC}$. These fluxes are comfortably above the $\nu$-fluxes in Eq. (2) derived from the IceCube data, hinting that the same cosmic-ray interactions produce the observed $\gamma$ rays and $\nu$'s.

Indeed, the Galactic Center has been considered as a plausible $\nu$ source in the past [10]. Estimates of the Galactic Center $\nu$-flux from $p\bar{p}$ interactions, with a steep $E^{-2.7}$ cosmic-ray spectrum based on observations on the Earth, resulted in steep $\nu$ spectrum similar to the atmospheric $\nu$-flux. This gave a Galactic Center $\nu$-flux estimate lower than the atmospheric $\nu$-flux models, which is inconsistent with IceCube observations as we have discussed earlier. We discuss below a likely origin of the hard-spectrum $\nu$-flux in Eq. (2) from the Galactic Center region.

The inner Galaxy is a host to active star-formation activity [11,12]. The $\sim 1.3 \times 10^{39} \, \text{erg/s}$ in cosmic-ray power at the Galactic Center [13] inferred from the supernovae rate, is far above the required bolometric $\nu$-luminosity of $\sim 4.1 \times 10^{34} \, \text{erg/s}$ within $\Omega_{GC}$, over one decade in energy, derived from Eq. (2). The acceleration of cosmic-rays in
the supernovae takes place over the Sedov time scale of a few thousand year. These cosmic-rays are trapped in the Galactic Center region and lose energy before escaping. The cooling time scale for the cosmic-ray protons due to $pp$ interactions, with an average cross-section $\sigma_{pp} = 60$ mb and inelasticity $k_{pp} = 0.5$, is

$$t_{pp} = (\sigma_{pp} n_H k_{pp})^{-1} \sim 1.2 \times 10^7 \left( \frac{n_H}{3 \text{ cm}^{-3}} \right)^{-1} \text{ year},$$

where $n_H \sim 3 \text{ cm}^{-3}$ is the average gas density within the central 1 kpc of the Galactic Center, enclosing a total gas mass of $M_H \sim 6 \times 10^7 M_\odot$. The escape time scale for the cosmic rays from within 8° of the Galactic Center region, with radius $R \sim 1.2$ kpc, in the Bohm diffusion limit is

$$t_{esc} = \frac{3 m_p^2 B_G}{2 T_{pp} B_{cr}} R^2 \sim 5.4 \times 10^6 \left( \frac{E_p}{10 \text{ PeV}} \right)^{-1} \left( \frac{B_G}{12 \mu \text{G}} \right) \left( \frac{R}{\text{kpc}} \right)^2 \text{ year},$$

where $B_G \sim 12 \mu \text{G}$ is the magnetic field in the Galactic Center region and $B_{cr} = 1.488 \times 10^{20} \text{ G}$ is the critical magnetic field for protons. A similar or longer escape time scale for cosmic rays with the maximum 10 PeV or lower energy, as compared to the $pp$ cooling time scale in Eq. (4), results in a hard cosmic-ray spectrum, essentially the same as the injected spectrum from the supernovae, in the Galactic Center region. The $\nu$ spectrum from the $pp$ interactions should therefore be hard too, as indicated by Eq. (2) derived from IceCube data. Note that this is the same $t_{acc} < t_{pp} \lesssim t_{esc}$ argument for the Fermi bubble $\gamma$-ray and $\nu$ spectra [14] [15], which are rather hard ($\Gamma \sim 2$).

The 3 shower-like $\nu$ events which are spatially correlated with the Fermi bubbles at relatively high Galactic latitudes, have energies in the $\sim 30–250$ TeV range. The $\gamma$-ray flux from the Fermi bubbles is also contamination-free and more reliable at high Galactic latitudes [1]. If hadronic mechanism is responsible for the bubble $\gamma$-ray flux, the 3 shower-like $\nu$ events could originate from the same cosmic-ray interactions. An order of magnitude estimate follows from the Fermi bubble $\nu$-fluxes predicted in Ref. [15]. At 100 TeV the $\nu$-flux on the Earth, with equal flavor ratios after oscillation, is $E^2 \Phi(\nu_e + \nu_\mu) \sim 2 \times 10^{-7} \text{ GeV sr}^{-1} \text{ cm}^{-2} \text{ s}^{-1}$ for the 10 PeV cosmic-ray energy cutoff case. Considering only half (at high Galactic latitudes) of the Fermi bubble solid angle, $\Omega_{FB/2} = 0.404$ sr, we calculate the number of 100 TeV shower-like $\nu$ events as

$$N_{FB/2} \sim E^2 \Phi(\nu_e + \nu_\mu) \Omega_{FB/2} (A_e + A_\tau) t_{live} \sim 1.1,$$

which is fewer than the number IceCube has detected. The 100 TeV $\nu$-flux from the Fermi bubbles could be a factor $\sim 2$–3 higher in principle, given the uncertainty on the $\gamma$-ray data and/or if cosmic-ray cutoff energy is $> 10$ PeV. A more detailed calculation of the $\nu$ events from the Fermi bubbles for the full IceCube will be presented elsewhere [16] [17].

The origin of the other 20 IceCube $\nu$ events, including a PeV shower-like event and all 7 track-like events is less clear. It was pointed out in Ref. [18] that up to 2 events could originate from the Galactic TeV unidentified sources. A pulsar wind nebula HESS J1825-137 and a supernova remnant G 0.9+0.1 near the Galactic Center have been considered as the origin of the IceCube $\nu$ events as well [19]. A general scenario of Galactic $\gtrsim 10$ PeV cosmic-ray interactions to produce IceCube PeV events [20] and plausible spectra of IceCube $\nu$ events as originating from Galactic cosmic-rays [21] have been considered as well. Some of the reported $\nu$ events, specially below PeV energy, could originate from extragalactic sources, such as jets inside GRB/hypernova progenitors [22] [23]. Ultrahigh-energy cosmic-ray interactions in the jets of AGNs [24] and GRBs [25], and/or during propagation in the CMB [26] could produce the observed PeV $\nu$ event(s). Finally, PeV scale dark-matter decay has been considered to explain IceCube $\nu$ events as well [28]. More data in future will be able to shed light on possible Galactic and extragalactic sources.

In summary, we have shown that cosmic-rays accelerated by supernovae in the Galactic Center region is likely the origin of 5 shower-like $\nu$ events detected by IceCube in the $\sim 0.1$-PeV range from this region. An additional 3 shower-like events may originate from the Fermi bubbles at high Galactic latitude. This scenario is consistent with hard spectrum $\gamma$-ray flux measured by Fermi-LAT from the inner Galaxy and from the Fermi bubbles, pointing to a common origin of $\gamma$ rays and $\nu$‘s from the Galactic cosmic-ray interactions.
