Measurement of electrons from semileptonic heavy-flavor hadron decays in pp collisions at $\sqrt{s} = 2.76$ TeV

ALICE Collaboration

Abstract

The $p_T$-differential production cross section of electrons from semileptonic decays of heavy-flavor hadrons has been measured at mid-rapidity in proton-proton collisions at $\sqrt{s} = 2.76$ TeV in the transverse momentum range $0.5 < p_T < 12$ GeV/c with the ALICE detector at the LHC. The analysis was performed using minimum bias events and events triggered by the electromagnetic calorimeter. Predictions from perturbative QCD calculations agree with the data within the theoretical and experimental uncertainties.
1 Introduction

The measurement of the production of heavy-flavor hadrons, i.e. hadrons carrying charm or beauty quarks, in proton-proton (pp) collisions provides a test of quantum chromodynamics (QCD), the theory of the strong interaction. In hadronic collisions, heavy quarks are almost exclusively produced through initial hard partonic scattering processes because of their large masses [1]. Consequently, the heavy-flavor hadron production cross sections are calculable in the framework of perturbative QCD (pQCD) down to very low transverse momenta ($p_T$).

Furthermore, heavy-flavor production cross sections measured in pp collisions provide a reference for corresponding measurements in high-energy nucleus-nucleus collisions, in which the formation of a strongly interacting partonic medium has been observed [2–9]. Heavy quarks are produced on short timescales, presumably before this medium is formed. Consequently, they probe the medium properties while they propagate through it [10–13]. In particular, the color charge and mass dependence of the partonic energy loss can be studied by comparing the suppression of heavy-flavor hadrons and hadrons carrying light quarks only [14, 15].

One available method to investigate heavy-flavor production is the measurement of the contribution of semileptonic decays of heavy-flavor hadrons to the inclusive electron spectra. This contribution is substantial because of branching ratios of the order of 10% into the semielectronic decay channel [16] and the large heavy-quark production cross sections at LHC energies [17,18]. In pp collisions at $\sqrt{s} = 7$ TeV, the signal of electrons from heavy-flavor hadron decays is of similar magnitude as the background [19] at an electron transverse momentum of $\approx 2$ GeV/c, and the ratio of signal to background increases with $p_T$.

The production of heavy-flavor hadrons was studied at the LHC in pp collisions at $\sqrt{s} = 7$ TeV in various channels by ALICE [17–21], ATLAS [22–24], CMS [25–31], and LHCb [32–35]. Perturbative QCD calculations [36–40] describe the measurements within the uncertainties.

For a center-of-mass energy of 2.76 TeV, which is the reference energy for Pb–Pb collisions in 2010 and 2011 at the LHC, ALICE already reported on the production of muons from heavy-flavor hadron decays in pp collisions at forward rapidity [13], and reconstructed open charm mesons at mid-rapidity [41]. Again, pQCD calculations describe the experimental data reasonably well. This paper presents a measurement of electrons, $(e^+ + e^-)/2$, from semileptonic decays of charm and beauty hadrons in the transverse momentum range $0.5 < p_T < 12$ GeV/c at mid-rapidity in pp collisions at $\sqrt{s} = 2.76$ TeV using the ALICE detector. The analysis technique employed here is similar to the one described in detail in [19], where the measurement in pp collisions at $\sqrt{s} = 7$ TeV is presented, and it consists of the following steps: selection of electron candidates, subtraction of the remaining hadron contamination, correction for efficiency and normalisation, and subtraction of the electron background originating from non-heavy-flavor sources.

2 Experimental setup and dataset

The ALICE experiment at the LHC is described in detail in [42], thus we only briefly introduce the detectors relevant for this analysis.

The detector closest to the interaction point is the Inner Tracking System (ITS). It consists of six cylindrical layers, grouped into three subsystems. The Silicon Pixel Detector (SPD) equips the two innermost layers, placed at radii of 3.9 cm and 7.6 cm from the beam axis. The spatial resolution of the detector is 12 $\mu$m in the transverse plane ($r\phi$) and 100 $\mu$m along the beam direction. The SPD is followed by two layers of the Silicon Drift Detector (SDD) and two layers of the Silicon Strip Detector at radii between 15 cm and 43 cm.
A large cylindrical Time Projection Chamber (TPC), which is the main tracking detector, surrounds the ITS at a radial distance between 85 cm and 247 cm. The chamber’s volume is filled with a mixture of Ne (85.7%), CO₂ (9.5%), and N₂ (4.8%) as drift gas. In the radial direction, the readout is divided into 159 pad rows. The TPC covers a pseudorapidity range of |\eta| < 0.9 for tracks having space points in the outermost pad rows. The specific energy deposit \(dE/dx\) is used to identify particles. The \(dE/dx\) resolution of the TPC (\(\sigma_{\text{TPC}-dE/dx}\)) is approximately 5.5% for minimum ionizing particles passing through the full detector [43].

The tracking detectors are housed inside a solenoidal magnet providing a homogeneous magnetic field of 0.5 T. The ITS and the TPC provide a transverse momentum measurement for charged particles with a resolution of \(\approx 1\%\) at 1 GeV/c and \(\approx 3\%\) at 10 GeV/c [44].

The Time-of-Flight detector (TOF) is located at a distance of 3.7 m from the beam axis covering the full azimuth and |\eta| < 0.9. The resolution of the particle arrival time is better than 100 ps. The collision time of the particle arrival time is estimated using the arrival time of the particles in the TOF detector. If also this second method does not provide a \(t_0\) measurement, the bunch crossing time from the LHC is used [41]. Particles are identified using the difference between the measured time-of-flight and the expected time-of-flight for a given particle species, normalized to the overall time-of-flight resolution \(\sigma_{\text{TOF-PID}} \approx 150\) ps [41], including both the resolution of the particle arrival time measurement and of the \(t_0\).

The Electromagnetic Calorimeter (EMCal) is a sampling calorimeter based on Shashlik technology spanning the pseudorapidity range |\eta| < 0.7 and covering 107° in azimuth [45]. The azimuthal coverage was limited to 100° for the data presented here. The EMCal supermodules comprise individual towers each spanning \(\Delta \phi \times \Delta \eta = 0.0143 \times 0.0143\) (6 × 6 cm). Each 2 × 2 group of neighboring EMCal towers forms a trigger elementary patch. The energy resolution was measured to be \(1.7 + 11.1/\sqrt{E(\text{GeV})} + 5.1/E(\text{GeV})\%\) [46], where \(\oplus\) indicates a sum in quadrature.

The V0 detector, used for online triggering and offline event selection, consists of two arrays of 32 scintillator tiles on each side of the interaction point. The detectors cover \(2.8 < \eta < 5.1\) and \(-3.7 < \eta < -1.7\), respectively.

The data used in this analysis were recorded in spring 2011. Two different data samples are available: a minimum bias sample and a sample triggered by the EMCal. In both samples, the SDD information was read out only for a fraction of the recorded events. The minimum bias trigger required at least one hit in either of the V0 detectors or the SPD. Background from beam-gas interactions was eliminated using the timing information from the V0 detector and the correlation between the number of hits and the reconstructed track segments in the SPD [47]. Events were required to have a reconstructed primary vertex [44] within \(\pm 10\) cm from the center of the detector along the beam direction. This covers 86% of all interactions. Pile-up events were identified as events having multiple vertices reconstructed in the SPD and they were rejected in this analysis. The probability of pile-up events was less than 2.5% in this data sample. The amount of remaining pile-up events after rejection was negligible in this analysis [19]. Before further event selection the minimum bias sample consisted of 65.8 M events, corresponding to an integrated luminosity \(L_{\text{int}} = 1.1\) nb\(^{-1}\). The use of the TOF information for particle identification required a stricter run selection which limited the integrated luminosity to 0.8 nb\(^{-1}\) (43.8 M events). In addition to the minimum bias sample, events selected by the EMCal trigger were analyzed. It required the coincidence of the minimum bias trigger condition described above and an energy sum in 2 × 2 EMCal trigger patches (4 × 4 towers) exceeding nominally 3 GeV. After event selection, the data sample recorded with the EMCal trigger corresponded to an integrated luminosity of \(L_{\text{int}} = 12.9\) nb\(^{-1}\).
3 Analysis

The minimum bias data sample was analyzed employing electron identification based on the information from the TPC [48]. At low transverse momentum ($p_T < 2 \text{ GeV/c}$) additional information from the TOF detector was required to improve the rejection of hadronic background. Electron identification in the analysis of the EMCal triggered data sample was based on the combined information from the TPC and the EMCal. The three analyses employing TPC, TPC-TOF, and TPC-EMCal electron identification, were conducted in different kinematical regions. In transverse momentum, the TPC analysis was restricted to the range $2 < p_T < 7 \text{ GeV/c}$, the TPC-TOF analysis was performed in the range $0.5 < p_T < 5 \text{ GeV/c}$, and the TPC-EMCal analysis was done in the range $2 < p_T < 12 \text{ GeV/c}$. In the latter case, the analysis used the minimum bias data sample for electron transverse momenta below $5 \text{ GeV/c}$ and an EMCal triggered data sample for electron $p_T$ above $4 \text{ GeV/c}$. In $p_T$ regions where the cross sections have been determined from more than one analysis the results were found to be consistent within uncertainties. Results from individual analyses were adopted for three different $p_T$ ranges. At low $p_T$ (up to $2 \text{ GeV/c}$), the TPC-TOF analysis provides the purest electron candidate sample. In the range $2 < p_T < 4.5 \text{ GeV/c}$, the result from the TPC analysis has smaller systematic uncertainties than both results from the TPC-TOF and the TPC-EMCal analyses. At high $p_T$ (above $4.5 \text{ GeV/c}$), the TPC and TPC-TOF analyses are statistics limited and the TPC-EMCal analysis of the EMCal triggered data sample provides the smallest uncertainty.

Table 1: Summary of the track selection cuts utilized in the different analyses. The same track selection cuts are applied in the TPC-TOF and the TPC analyses.

Reconstructed tracks were selected for the analysis using the criteria listed in Table 3, which are similar to those used in the analysis described in [19]. In particular, the cut on the minimum number of ITS clusters was reduced to three (instead of the value of four used in [19]) because the SDD points, which were not available for a sizeable fraction of the events, were excluded from the track reconstruction used for this analysis, thus limiting the maximum number of hits in the ITS to four. In order to reduce wrong associations between candidate tracks and hits in the first layer of the SPD, hits in both layers of the SPD were required in the TPC-TOF analysis. In the TPC-EMCal analysis, this requirement has been relaxed to at least one hit in any of the two SPD layers in order to increase the statistics, thus resulting in a larger background. A cut on the minimum distance to the primary vertex was not imposed because electrons from charm hadron decays are indistinguishable from electrons originating from the primary vertex.

Three methods were used to identify electrons: in both the TPC and the TPC-TOF analyses, electrons were identified via their specific energy deposition ($dE/dx$) in the TPC. Tracks were required to have a $dE/dx$ between one standard deviation below and three standard deviations above the expected $dE/dx$ of electrons, consistent with an electron identification efficiency of $\approx 85\%$. In the TPC analysis for $p_T \geq 2 \text{ GeV/c}$, a more stringent cut was applied in order to cope with the increasing hadron contamination towards higher momenta. Therefore, electron candidate tracks were required to have a $dE/dx$ between 0.5 standard deviations below and three standard deviations above the mean $dE/dx$ for electrons, correspond-

ing to a selection efficiency of ≈ 70%. For pT < 2 GeV/c, in the TPC-TOF analysis, the TOF detector was used in addition to the TPC. Here tracks were required to have a time-of-flight consistent with the expected time-of-flight for electrons within 3 standard deviations σTOF−PID, thus rejecting protons and kaons at momenta where they cannot be distinguished from electrons via dE/dx alone.

For pT ≥ 4.5 GeV/c, the TPC-EMCal analysis was employed. In the TPC, a dE/dx between 1.4 standard deviations below and three standard deviations above the mean dE/dx for electrons was required, corresponding to an electron identification efficiency of ≈ 90%. Tracks were extrapolated from the TPC to the EMCal surface and geometrically associated with EMCal clusters within 0.02 both in η and in φ. The ratio of the energy of the matched cluster in the EMCal to the momentum measured with the TPC and ITS (E/p) was required to be within 0.8 and 1.4 for electron candidates, corresponding to an identification efficiency of ≈ 60% averaged over pT.

The hadronic background was estimated using a parameterization of the TPC dE/dx in various momentum slices [19] or, alternatively, the E/p distribution of identified hadrons, and it was subtracted from the electron candidate sample. For the TPC-TOF/TPC analysis the hadron contamination was negligible for pT ≤ 2 GeV/c and less than 1.5% for pT ≤ 4.5 GeV/c. In the TPC-EMCal analysis, the hadron contamination was negligible for pT ≤ 6 GeV/c, remained below 10% for pT ≤ 8 GeV/c, and it increased to ≈ 40% at pT = 12 GeV/c.

The pT-differential invariant yield of inclusive electrons per minimum bias event has been obtained by dividing the raw yield of electrons, (e^+ + e^-)/2, measured in pT bins of widths ΔpT, by the number of minimum bias events, by the width Δy of the covered rapidity interval, and by the product of the geometric acceptance εgeo, the reconstruction efficiency εreco, and the electron identification efficiency εeID. In the TPC-TOF/TPC analyses, εgeo, εreco, and εeID in TOF were obtained using a Monte Carlo simulation. Proton-proton events at √s = 2.76 TeV were generated with the PYTHIA 6.4.21 event generator [49]. Two samples were used for the efficiency calculation: a minimum bias sample based on the Perugia-0 tune [50] and a heavy-flavor enhanced sample containing only events with at least one c ¯c or b ¯b pair. The enhanced sample provided a sufficient number of tracks for efficiency determination in the pT region above 4 GeV/c. Tracks were propagated through the detector using GEANT3 [51]. The electron selection efficiency in the TPC (εID) was extracted from data using the measured mean dE/dx and the width of the dE/dx distribution for electrons. The product of acceptance and efficiency was ≈ 0.3, with a mild dependence on pT. In the TPC-EMCal analysis, the reconstruction efficiency was obtained in a similar way to the
TPC-TOF/TPC analyses, and the electron selection efficiency was determined again from data utilizing the measured mean $dE/dx$.

In addition, a correction for the trigger bias was applied in the EMCal triggered data sample. This correction was determined from the ratio of the EMCal cluster energy distribution in triggered data compared to those in minimum bias data. The resulting rejection factor at high energy (above the nominal trigger threshold of 3 GeV) was determined to be $1180 \pm 10$. The trigger efficiency is shown in Fig. 1 as a function of the cluster energy [52]. The trigger efficiency obtained from data is well-reproduced by a simulation which incorporated the supermodule-by-supermodule variation in the trigger turn-on curves and took into account the trigger mask employed in data. The statistics of the minimum bias data sample were such that a precise measurement of the trigger efficiency for electrons as a function of track $p_T$ was not possible. Thus, the trigger simulation was used to generate a trigger efficiency for electrons as a function of track $p_T$. Above 5 GeV the trigger efficiency is $\approx 85\%$, limited by the trigger mask.

The precision of the transverse momentum measurement is limited by the momentum resolution and it is affected by the energy loss of electrons via Bremsstrahlung in material. To correct for the resulting distortion of the shape of the inclusive electron $p_T$ distributions, an unfolding procedure based on Bayes’ theorem [53] was used.

In order to evaluate the systematic uncertainty, the analysis was repeated with modified track selection and particle identification criteria. Table 3 gives an overview of the systematic uncertainty assigned to various contributions. The total systematic uncertainty of the TPC-TOF/TPC analysis is less than 6% for $p_T < 4.5$ GeV/$c$. The systematic uncertainty of the TPC-EMCal analysis grows from 10% at 4.5 GeV/$c$ to 20% at 12 GeV/$c$.

Apart from the signal, the inclusive electron $p_T$ spectrum contains background from various sources: conversion of photons including direct photons, Dalitz decays of light mesons, dielectron decays of vector mesons, and semileptonic decays of kaons ($K\pi\pi$). The ratio of signal to background ($S/B$) depends strongly on $p_T$. While at low $p_T$ the background dominates the inclusive electron yield ($S/B \approx 0.2$ at $p_T = 0.5$ GeV/$c$) the signal becomes more prominent with increasing $p_T$ ($S/B > 1$ for $p_T > 2.5$ GeV/$c$). The background was estimated using a cocktail calculation as described in detail in [19]. The main cocktail input is the measured $p_T$-differential production cross section of neutral pions [54]. More than 80% of the electron background can be attributed to $\pi^0$ Dalitz decays and the conversion of photons.

ALICE Collaboration

Fig. 2: $p_T$-differential invariant yield of inclusive electrons compared to the electron background cocktail for the TPC-TOF/TPC analysis (left) and the TPC-EMCal analysis (right). Ratios of the inclusive electron yields to the respective cocktail are shown in the lower panels.

The electron background cocktails were statistically subtracted from the inclusive electron distributions obtained in the three analyses. The $p_T$-differential cross section of electrons from heavy-flavor hadron decays was obtained by normalizing the invariant yield to the minimum bias cross section, which is $55.4 \pm 1.0$ mb [58]. The final $p_T$-differential cross section presented here is a combination of the results from the three analyses as summarized in Table 3. In the $p_T$ ranges in which the analyses overlap the results are in agreement within their uncertainties.

Fig. 3: (Color online) $p_T$-differential cross section of electrons from heavy-flavor hadron decays compared to pQCD calculations from FONLL (red) [36, 59, 60], GM-VFNS (blue) [37, 39, 61, 62] and $k_T$-factorization (green) [40, 63, 71]. Uncertainties on the theory calculations originate from the variation of the factorization and the renormalization scales and from the heavy-quark masses. The ratios data/theory are shown in the lower panels, where the dashed lines indicate the additional theoretical uncertainties relative to unity.
4 Results

The $p_T$-differential invariant production cross section of electrons from heavy-flavor hadron decays at mid-rapidity in pp collisions at $\sqrt{s} = 2.76$ TeV is shown in comparison to pQCD calculations from FONLL [36, 59, 60], GM-VFNS [37–39, 61, 62], and $k_T$-factorization [40, 63–71] in Fig. 3. Statistical and systematic uncertainties of the data are shown separately as error bars and boxes, respectively. Dashed lines indicate the uncertainties of the pQCD calculations originating from the variation of the factorization and normalization scale as well as of the heavy-quark masses [36, 38–40]. As seen in the lower panels of Fig. 3, all pQCD calculations are consistent with the measured cross section over the full $p_T$ range within combined experimental and theoretical uncertainties. According to the FONLL calculation, this range of the electron transverse momentum includes approximately 50% of the charm and 90% of the total beauty cross section at mid-rapidity. The latter contribution starts to dominate from approximately 4-5 GeV/c towards higher transverse momenta.

5 Summary

The inclusive differential production cross section of electrons from charm and beauty hadron decays was measured with ALICE in the transverse momentum range $0.5 < p_T < 12$ GeV/c at mid-rapidity in pp collisions at $\sqrt{s} = 2.76$ TeV, which is the same center-of-mass energy as the one available so far in Pb–Pb collisions at the LHC. pQCD calculations are in good agreement with the data. The measurement presented in this article improves the reference cross section of electrons from heavy-flavor hadron decays used for the measurement of the corresponding nuclear modification factor in Pb–Pb collisions, where the current reference is obtained by scaling the cross section measured in pp collisions at $\sqrt{s} = 7$ TeV to 2.76 TeV using FONLL pQCD calculations [72].
