(Dated: October 28, 2015)

The astrophysical S-factor for the radiative capture \(d(p, \gamma)^3\)He in the energy-range of interest for Big Bang Nucleosynthesis (BBN) is calculated using an ab-initio approach. The nuclear Hamiltonian retains both two- and three-nucleon interactions - the Argonne \(v_{18}\) and the Urbana IX, respectively. Both one- and many-body contributions to the nuclear current operator are included. The former retain for the first time, besides the \(1/m\) leading order contribution (\(m\) is the nucleon mass), also the next-to-leading order term, proportional to \(1/m^3\). The many-body currents are constructed in order to satisfy the current conservation relation with the adopted Hamiltonian model. The hyperspherical harmonics technique is applied to solve the \(A = 3\) bound and scattering states. A particular attention is used in this second case in order to obtain, in the energy range of BBN, an uncertainty on the astrophysical S-factor of the order or below \(\sim 1\%\). Then, in this energy range, the S-factor is found to be \(\sim 10\%\) larger than the currently adopted values. Part of this increase (1–3 \%) is due to the \(1/m^3\) one-body operator, while the remaining is due to the new more accurate scattering wave functions. We have studied the implication of this new determination for the \(d(p, \gamma)^3\)He S-factor on deuterium primordial abundance. We find that the predicted theoretical value for \(^2\)H/H is in excellent agreement with its experimental determination, using the most recent determination of baryon density of Planck experiment, and with a standard number of relativistic degrees of freedom \(N_{\text{eff}} = 3.046\) during primordial nucleosynthesis.

PACS numbers: 26.35.+c,25.10.+s,98.80.Ft

Introduction. The radiative capture \(d(p, \gamma)^3\)He is a relevant process in many astrophysical environments. For instance, it is the second step in the chain of nuclear reactions which, starting from the proton-proton weak capture, allows to stars like our Sun to shine via pp-chain. Interest in this reaction is also present in the context of Big Bang Nucleosynthesis (BBN), see e.g. Ref. [1] and references therein, since it is one of the main processes through which deuterium can be destroyed and thus affects its eventual yield. BBN is a powerful method to test the validity of the cosmological model at the MeV energy scale. For a given set of values of leading nuclear reaction rates, primordial element abundances depend upon two key cosmological parameters, the energy density in baryons, \(\Omega_b h^2\), and the energy density of relativistic species \(\rho_{\text{rel}}\) or equivalently, the effective neutrino number, \(N_{\text{eff}}\), defined as \(\rho_{\text{rel}} = \rho_\gamma \left(1 + \frac{7}{8} \left(\frac{4}{11}\right)^{4/3} N_{\text{eff}}\right)\) where \(\rho_\gamma\) is the Cosmic Microwave Background (CMB) photon energy density. The benchmark value for this parameter with only three active neutrinos contributing is \(N_{\text{eff}} = 3.046\) [2].

The baryon energy density has been measured with a remarkable precision by CMB anisotropy experiments, so in the minimal \(\Lambda\)CDM scenario light nuclei abundances are basically fixed [3]. Using the most recent determination of the Planck satellite experiment, \(\Omega_b h^2 = 0.02225 \pm 0.00016\) [3], and the public BBN code \texttt{Ar}t\texttt{Eno}PE [4], the primordial deuterium to hydrogen ratio is predicted to be \(^2\)H/H=(2.60\pm0.07) \times 10^{-5}\) (68 \% C.L. error). Notice that this determination is lower than before, due to the order 1\% increase of \(\Omega_b h^2\) with respect to Planck 2013 results. The theoretical uncertainty quoted above is almost fully due (more than 90 \%) to present errors on experimental determination of the \(d(p, \gamma)^3\)He cross section.

This result is in agreement at 1-\(\sigma\) with the recent determination of Ref. [4] where, through a new analysis of all known deuterium absorption-line systems, it was found \(^2\)H/H=(2.53 \pm 0.04) \times 10^{-5}\) at 68 \% of C.L., but it is slightly larger. A possible way to get an even better agreement between the two values is to slightly decrease the effective neutrino number down to \(N_{\text{eff}} \sim 2.84\). Another way is to increase the value of the \(d(p, \gamma)^3\)He astrophysical S-factor. This possibility was first explored in Ref. [6] and then analyzed in details in Ref. [7], using Planck 2013 data release, and in Ref. [8]. The conclusion of these studies is that increasing the \(d(p, \gamma)^3\)He thermal rate in the BBN temperature range by a factor of order 10 \% leads to a very good agreement between CMB anisotropy results and primordial deuterium abundance. Therefore, a better determination of this \(S\)-factor with a reduction of the corresponding uncertainty in the BBN energy range, i.e. \(E \simeq 30 – 300\) keV, would be extremely important.

The astrophysical \(S\)-factor at low energy, around the solar Gamow peak \(E_G \simeq 9\) keV, is well known, thanks to the results of the LUNA experiment [8]. However, for the BBN relevant energy range, the experimental situation is rather unclear, since the only available experimental data [9] are quite in disagreement with the polynomial
best fit of \( S(E) \) for \( E \simeq 0 \rightarrow 2 \text{ MeV} \) \[10\]. This gives rise to an uncertainty on the cross section at the level of 6–10 \%. This is the main motivation behind the experiment recently proposed by the LUNA Collaboration, which has the goal of measuring the \( d(\gamma,p)^3\text{He} \) astrophysical \( S \)-factor in the BBN energy range with a 3 % accuracy. A feasibility test has already been performed \[11\].

On the other hand, the \( d(\gamma,p)^3\text{He} \) astrophysical \( S \)-factor can be calculated using a microscopic \textit{ab-initio} approach. In fact, in Refs. \[12 \ 13\] (see also references therein) the hyperspherical harmonics (HH) technique was used to solve for the \( A = 3 \) nuclear wave functions using a realistic description of the nuclear interaction, which includes both two- and three-nucleon interactions. These are constructed to reproduce the \( A = 2 \) large body of experimental data with a \( \chi^2 \)/datum \( \sim 1 \) (the Argonne v18 - AV18 - model \[14\]), and the \( A = 3 \) binding energies (the Urbana IX - UIX - model \[15\]). Note that the HH method (see Ref. \[16\] for a review) is the only available one able to calculate the nuclear wave function for the initial \( p - d \) scattering state at low energies, as the ones of interest here, including the Coulomb interaction between the charged initial particles. In the latest study of Ref. \[13\], a realistic model for the nuclear current operator was used, retaining both one- and many-body contributions. The latter are necessary in order to maintain gauge invariance in the presence of a system of interacting particles, and in Ref. \[13\] all the effort was put to construct these contributions which exactly satisfy the current conservation relation in conjunction with the AV18/UIX potential. The former, instead, was simply obtained performing a \( 1/m \) expansion (\( m \) is the nucleon mass) of the single-nucleon covariant operator, and retaining the leading order contribution. The many-body contributions were found already in Ref. \[12\] essential to reach an excellent agreement with the LUNA data \[8\] around the solar Gamow peak \[10 \ 13\]. In the energy range of interest for BBN, on the other hand, the theoretical predictions of Ref. \[13\] were found to be 2–10 \% higher than the central value for the polynomial fit of Ref. \[10\]. In the present letter, our starting point is the work of Ref. \[13\], which, although very accurate, should be considered incomplete for two reasons: (i) no estimate of the theoretical uncertainty was given, in particular that one arising from the solution of the \( p - d \) scattering problem with the HH method; (ii) the one-body terms beyond the leading order operator, of the order \( 1/m^3 \), were found few years later \[17\] essential in order to get a reasonable agreement between theory and experiment for a related process, the \( d(n,\gamma)^3\text{He} \) radiative capture. Given the similarities between the \( p - d \) and \( n - d \) radiative captures, it is to be expected that these \( 1/m^3 \) one-body contributions might be important also for the process here under consideration. The goal of the present letter is to address the two above mentioned issues and to verify whether the new prediction for the \( d(\gamma,p)^3\text{He} \) astrophysical \( S \)-factor goes in the direction of improving the consistency of theoretical BBN deuterium abundance prediction, the new Planck results, and the experimental data of Ref. \[5\]. We do not consider here \( ^4\text{He} \) primordial mass fraction \( Y_p \), since it is insensitive to this reaction rate. For example, a change of the \( d(\gamma,p)^3\text{He} \) \( S \)-factor by a factor two affects \( Y_p \) at the level of 0.04 \%, too small to be appreciated with present statistical and systematic uncertainties on its experimental determination, see e.g. Ref. \[18\].

\textit{The present calculation.} We discuss here the two significant improvements in the calculation with respect to Ref. \[12\]. First of all, in the present work, we pay particular attention to the numerical determination of the \( p - d \) wave function. In particular, in each \( L,S,J \) channel (\( L \) is the \( p - d \) orbital angular momentum, \( S = 1/2, 3/2 \) is the \( p - d \) total spin, and \( J = L + S \)) the wave function \( \Psi^{LSJ} \) has been tested calculating \( \langle H \rangle \equiv \langle \Psi^{LSJ} | H | \Psi^{LSJ} \rangle \) in a box with a radius of 70 fm, using a Monte Carlo method (independently on our technique to determine \( \Psi \) and verifying that the correct result \( \langle H \rangle = E - B_d \) is obtained within the requested accuracy (here \( E \) is the \( p - d \) center-of-mass energy and \( B_d \) the deuterium binding energy). Different grid points, dimensionality of the HH expansion basis and values for the non-linear parameter entering the polynomial expansion of the hyperradial functions (see Ref. \[16\]) have been checked in order to verify the above relation within 0.1 %. With this procedure we were able to reduce the numerical uncertainty relative to the wave functions in our astrophysical \( S \)-factor estimates of better than 1 \% for the whole energy range here under consideration (see Table I). To be noticed, that the nuclear Hamiltonian used in the present study is the same as that of Ref. \[13\], i.e., it retains the AV18/UIX potential model, which allows to nicely reproduce, using the HH method, the \( ^3\text{He} \) binding energy and many \( A = 3 \) scattering observables. Some discrepancies between the AV18/UIX predictions and experiment arise only for some delicate polarization and breakup observables. Therefore, the shortcomings of the adopted interaction model are expected to be of no consequences for the present study. Furthermore, all partial waves with \( J \leq 5/2 \) and both parities have been retained.

The new term of the nuclear electromagnetic current here included is that arising from the \( 1/m \) expansion of the single-nucleon covariant current operator, and is a relativistic correction of the order \( 1/m^3 \). It has been derived in Refs. \[19 \ 20\] in the context of chiral effective field theory, and can be written as \[19\]

\[
j_{RC}^i = \frac{e}{8m^3} \varepsilon_i \left[ 2 \left( K_i^2 + q^2/4 \right) (2K_i + i\sigma_i \times q) + K_i \cdot q (q + 2i\sigma_i \times K_i) \right] - \frac{ie}{8m^3} \kappa_i \left[ K_i \cdot (4\sigma_i \times K_i - iq) \right]
\]
\[
- (2iK_i - \sigma_i \times q) q^2/2 + 2(K_i \times q) \sigma_i \times K_i \]

where \(K_i = (p'_i + p_i)/2\), \(p_i\) and \(p'_i\) being the initial and final momenta of the nucleon, \(q\) is the photon momentum, \(e_i = (1 + \tau_{i,z})/2\), the charge-projection isospin operator, \(\kappa_i = (\kappa_S - \kappa_V \tau_{i,z})/2\), \(\kappa_S = -0.12\mu_N (\text{keV} = 3.706\mu_N)\) being the isoscalar (isovector) combination of the anomalous magnetic moments of proton and neutron, and \(\sigma_i (\tau_i)\) are the spin (isospin) Pauli matrices. It was found in Ref. [17] that \(J^{RC}\) reduces the \(n-d\) total cross section at thermal energies of about 4-5\%, bringing the theoretical prediction in a much better agreement with the experimental datum (within 4\%). In the \(p-d\) case, instead, we have found that the operator \(J^{RC}\) gives a positive contribution, increasing the astrophysical \(S\)-factor of 1-3\% over the whole energy range considered here (see Table I).

TABLE I: The \(p-d\) astrophysical \(S\)-factor (in keV b) for a representative set of energy values \(E\) (in keV). The theoretical percent uncertainty arising from the solution of the \(p-d\) scattering problem with the HH method is given in the second column \((\Delta S_{WF})\), while the additional contribution due to the one-body term of Eq. [1] \((\Delta J^{(RC)})\) is given in the last column, also in percent. Note that for \(E=2\) MeV (last row), the value for \(\Delta S_{WF}\) is below the permil level, and therefore not quoted.

The astrophysical \(S\)-factor obtained in the present work is listed in Table I and plotted in Fig. 1, where it is compared with the previous calculations of Ref. [13], as well as with the existing data of Refs. [8, 9, 21, 22] and the polynomial best fit of Ref. [10]. To be noticed that the theoretical uncertainty arising from the solution of the \(p-d\) scattering problem with the HH method are not visible on the plot, although the corresponding symbols retain an error. The present results are systematically larger (about 8-10\%) than those of Ref. [13]. We have investigated the origin of such an increase, and we have found that only 1-3\%, depending on the energy value, is due to the one-body \(1/m^3\) contribution. Therefore, the remaining 5-8\% is due to the new solutions of the \(A = 3\) (scattering) problem. In fact, the present wave functions have been obtained with the same HH technique as in Ref. [13], but with the goal of reaching a required higher accuracy, as dictated by BBN, and therefore they have been tested one by one, as explained above.

**Implications for BBN.** To study the effect of the new \(ab-initio\) determination of the \(d(p, \gamma)\)\(^3\)He \(S\)-factor on primordial deuterium produced during BBN we have computed the corresponding thermal rate using the best fit values reported in the second column of Table I and modified the numerical code PArthENOE [4] accordingly. The theoretical results for deuterium to hydrogen density ratio \(^2\)H/\(^1\)H\(_b\) are then computed as function of two parameters, the baryon density \(\Omega_b h^2\) and \(N_{\text{eff}}\) and compared with the experimental determination \(^2\)H/\(^1\)H\(_{\text{exp}}\) of Ref. [5]. To obtain the best fit values and uncertainty on these parameters we then consider the likelihood function

\[
\mathcal{L}(\Omega_b h^2, N_{\text{eff}}) = \mathcal{L}_{\text{Planck}}(\Omega_b h^2) \times \exp \left( -\frac{(2H/\sigma_{\text{exp}}^2) - (2H/\sigma_{\text{th}})^2}{2(\sigma_{\text{exp}}^2 + \sigma_{\text{th}}^2)} \right),
\]

(2)
where $\sigma_{exp} = 0.04$ as obtained in Ref. [5], $L_{\text{Planck}}(\Omega_b h^2)$ is a Gaussian prior corresponding to the Planck result of Ref. [3], while $\sigma_{th}$ is the propagated error on deuterium yield due to the present experimental uncertainty on other leading nuclear reactions relevant for deuterium production and destruction during BBN, namely $d(d, n)^3\text{He}$ and $d(d, p)^3\text{H}$. It also accounts for the $d(p, \gamma)^3\text{He} S$-factor theoretical uncertainty of Table I and the small error on the $p(n, \gamma)d$ rate, both very sub-dominant with respect to the other error sources.

For the Planck 2015 value of $\Omega_b h^2$ and standard $N_{\text{eff}}$ we get $^4\text{H}/H_{th} = 2.49 \pm 0.03 \pm 0.03$, where the two errors are due to nuclear rate and $\Omega_b h^2$ uncertainties, respectively. In Fig. 2 we show the likelihood contours (68, 95 and 99% C.L.) in the $\Omega_b h^2-N_{\text{eff}}$ plane from $^4\text{H}/H$, with the Planck 2015 prior on $\Omega_b h^2$, a free $N_{\text{eff}}$ and using the experimental result of Ref. [5]. The triangle is the best fit value of Planck 2015 results for these parameters, with corresponding 68% C.L. error bars [3].

FIG. 2: (Color online) The likelihood contours (68, 95 and 99 % C.L.) in the $\Omega_b h^2-N_{\text{eff}}$ plane from $^4\text{H}/H$, with the Planck 2015 prior on $\Omega_b h^2$, a free $N_{\text{eff}}$ and using the experimental result of Ref. [5]. The triangle is the best fit value of Planck 2015 results for these parameters, with corresponding 68% C.L. error bars [3].

Summary and Outlook. The astrophysical $S$-factor for the $d(p, \gamma)^3\text{He}$ reaction is crucial to determine the consistency of BBN theoretical prediction for deuterium abundance, the new Planck results, and the most recent experimental determination of such abundance [5]. In the absence of an accurate experimental determination in the energy range of interest for BBN, 30-300 keV, we have performed a new theoretical $ab$-initio calculation, using the most up-to-date techniques to calculate the wave functions for the initial scattering and final bound states, with the realistic AV18/UIX potential model, as well as the most up-to-date realistic model for the nuclear current operator, which satisfies gauge invariance with the adopted Hamiltonian and retains the $1/m^3$ contribution in the one-body operator. We have found that the numerical uncertainty relative to the wave function in the $S$-factor is lower than 1 %, while the $1/m^3$ one-body contribution increases the $S$-factor by 1–3 % over the whole energy range. We have then investigated the effect of this new $ab$-initio determination on the primordial deuterium abundance. We find that BBN predictions are in very good agreement with the Planck 2015 results and the experimental result of [5]. Also the inferred value for $N_{\text{eff}}$ is fully consistent with a standard radiation content during BBN. Of course, our results ought to be confirmed by direct measurement of the $d(p, \gamma)^3\text{He} S$-factor, as it is planned at the Gran Sasso National Laboratories (Italy), by the LUNA Collaboration. Such a measurement will therefore turn out to be crucial in this context and an improved accuracy at few percent would provide an independent handle to assess the overall consistency of the standard cosmological model. Finally, it should be mentioned that a theoretical $ab$-initio calculation of this process is at reach also within the so-called chiral effective field theory ($\chi$EFT) framework, which provides, on one hand, a direct connection between quantum chromodynamics (QCD) and the strong and electroweak interactions in nuclei. On the other hand, it is a practical calculational scheme, which can be improved systematically. This allows, in principle, to obtain predictions on a more fundamental basis. The first studies along this line have been done for the electromagnetic structure of light nuclei [23, 24]. At present, however, the consistency between the $\chi$EFT nuclear potentials and electromagnetic currents necessary to satisfy exactly gauge invariance (as in the case of the calculation presented here) has not been yet achieved, making the $\chi$EFT results not completely reliable at the accuracy level necessary for BBN predictions. Work on this issue, though, is currently underway.
