The minimal seesaw scenario can radiatively generate the Higgs potential to induce electroweak symmetry breaking while supplying an origin of the Higgs vacuum expectation value from an underlying Majorana scale. If the Higgs potential and (derived) electroweak scale have this origin, the heavy SU(3) × SU(2) × U(1)Y singlet states are expected to reside at \( m_N \sim 10 - 500 \text{ PeV} \) for couplings \( |\omega| \sim 10^{-3.5} - 10^{-6} \) between the Majorana sector and the Standard Model. In this framework, the usual challenge of the electroweak scale hierarchy problem with a classically assumed potential is absent as the electroweak scale is not a fundamental scale. The new challenge is the need to generate or accommodate PeV Majorana mass scales while simultaneously suppressing tree-level contributions to the potential in ultraviolet models.

I. Introduction. The Standard Model (SM) provides a successful description of many particle physics measurements but does not explain the experimental evidence for dark matter and neutrino masses. These facts argue for extensions of the SM that experience some form of decoupling in an Effective Field Theory (EFT) setting so that the corrections to the SM in an effective field theory (SMEFT) framework are small perturbations.

Minimal (viable) extensions of the SM are usually based on the inability to address the Electroweak (EW) scale hierarchy problem. A SMEFT statement of which set with an inability to address the Electroweak (EW) theory (SMEFT) framework are small perturbations.

The scenario presented is falsifiable and depends in a sensitive manner on the measured value of the top quark and Higgs masses, and the detailed neutrino mass spectrum. Higher order Renormalization Group Equations (RGEs) and threshold matching calculations are also critical in this scenario. This approach strongly motivates more theoretical and experimental progress in all of these areas in order to falsify or confirm this possible origin of the Higgs potential and EW scale.

II. Seesaw model and threshold corrections. We use the seesaw formalism of Refs. [8] [9]. The extension of the SM Lagrangian with \( p, q = \{1, 2, 3\} \) singlet fields \( N_p \) is given by

\[
2\mathcal{L}_{N_p} = \overline{N_p} (i\partial - m_p) N_p - \ell_\beta^T \mathcal{H} \omega_\beta^p N_p, \\
- \ell_\beta^T \mathcal{H} \omega_\beta^p \ell_\beta \mathcal{H} N_p - \overline{N_p} \omega_\beta^a \ell \ell \mathcal{H} N_p - \overline{N_p} \omega_\beta^a \ell \ell \mathcal{H} N_p.
\]

The \( \omega_\beta^p = \{x_\beta, y_\beta, z_\beta\} \) are each complex vectors in flavour space. These vectors have absorbed the Majorana phases \( \theta_\beta \). The mass eigenstate Majorana fields are defined such that they satisfy the Majorana condition \([6]\): \( N_p^c = N_p \). These fields are related to chiral right handed fields \( N_R \) that are singlets under \( SU(3) \times SU(2)_L \times U(1)_Y \) as \([3]\)

\[
N_p = e^{i\theta_p/2} N_{R,p} + e^{-i\theta_p/2} (N_{R,p})^c.
\]

The superscript \( c \) stands for charge conjugation; defined on a four component Dirac spinor as \( \psi^c = -i\gamma_2 \gamma_0 \psi^T \). Integrating out the seesaw model at tree level, the results can be mapped to the SMEFT up to dimension seven \([8]\). The threshold corrections of interest lead to dimension two and four terms. They come about due to integrating out the heavy \( N_p \) states at one loop and running down to the scales that are used to experimentally probe the SM states and interactions in the EW vacuum. The diagrams of Fig.\([1]\) give a threshold matching to the Higgs potential terms

\[
V(H^+ H) = -\frac{m_N^2 |\omega_p|^2}{16 \pi^2} F_1 H^+ H - \lambda_{pq} F_2 (H^+ H)^2,
\]

\( F_1 \) and \( F_2 \) are fields in the SM.
where

$$F_1 = 1 + \log \frac{\mu^2}{m_p^2},$$  

$$F_2 = 1 - \frac{m_p m_q}{m_\pi^2} \log \frac{m_q^2 m_p^2}{m_\pi^2} + \frac{m_q^2 \log m_p^2 - m_p^2 \log m_q^2}{(m_p^2 - m_q^2)}.$$  

and $\lambda_{pq} = 5 (\omega_q \cdot \omega_{p*})(\omega_p \cdot \omega_{q*})/(64 \pi^2)$. Here the repeated indices are summed over and the results can be compared to past results in Ref. [10][11]. We have used dimensional regularization in $d = 4 - 2\varepsilon$ dimensions and MS here and below. The counterterms of the SM and the full theory including the $N_p$ states cancel the $\epsilon$ divergences in each case. The mismatch of the SMEFT Lagrangian and the full theory in the limit $p^2/m_p^2 \to 0$ (with kinematic invariants denoted $p^2$) defines the threshold matching. The renormalization scale dependent logs in the result can be neglected when also neglecting the (net) two loop effects due to running between the threshold matchings.

Considering the parameterization of the Higgs potential ($V_c$) as

$$V_c(H^+ H) = -\frac{m^2}{2} (H^+ H) + \lambda (H^+ H)^2,$$

neglecting the effect of running down from the scale(s) $\mu = m_p$, and assuming the mass differences are parametrically smaller than intrinsic mass scales in the Majorana sector ($(m_q^2 - m_p^2)/m_p q < 1$) we find

$$\Delta m^2 = m_p^2 \frac{|\omega_p|^2}{8 \pi^2}, \quad \Delta \lambda = -5 \frac{(\omega_q \cdot \omega_{p*})(\omega_p \cdot \omega_{q*})}{64 \pi^2}.$$  

Note that the $\lambda$ threshold corrections can be subdominant to other quantum corrections in the full CW potential in the parameter space of interest where $|\omega_p| \ll 1$ and $m_p \gg 246 \text{ GeV}$.

III. Induced CW potential. The threshold corrections to $H^+ H$ can be naturally dominant in defining the Higgs potential below the scales $\mu \simeq m_p$. The reason is that the SM is classically scale invariant in the limit that the vacuum expectation value (vev) of the Higgs $v \to 0$ [11][13][14] ($m \to 0$ in Eqn. 6). This point of enhanced symmetry is anomalous, even before its soft breaking by the threshold matching. However, the additional SM breakings of scale invariance through quantum corrections are associated with dimensionful parameters that are smaller than $m_p^2$ in a consistent version of this scenario at the threshold matching scale.

A breaking of the scaleless limit of the SM is due to QCD, which generates the scale $\Lambda_{QCD}$ by dimensional transmutation [17] at low scales as ($\Lambda_{QCD}/\mu)^{b_0} = \exp[-8 \pi/hQCD^2(\mu)]$ where $b_0 = 11 -(2/3) n_f$ [12][13]. The quark masses that result lead to $V_c$ contributions such as

$$\Delta m^2 = \frac{N_c g^2}{32 \pi^2} \left[ 1 + \log \left( \frac{\mu^2}{\Lambda_{QCD}^2} \right) \right] + \cdots$$

which subsequently induces a vev for the Higgs, leading to gauge boson masses $\propto \Lambda_{QCD}$. As we are assuming $m_p^2 |\omega_p|^2 \gg \Lambda_{QCD}^2$ for each $p$ these contributions are naturally subdominant for $H^+ H$, and anyway, at the threshold matching scale we consider, the QCD coupling has run to scales such that $g_3(\mu) < 1$. Renormalization of the CW potential also introduces an anomalous breaking of scale invariance. Consider defining $V_{CW}(H^+ H)$ as the one loop CW potential expanding around the scaleless limit of the SM while neglecting the threshold corrections. The standard result [11][14][15] can be minimized via $\partial V_{CW}/\partial (H^+ H) = 0$. The vev scale obtained is exponentially separated from the renormalization scale. This scale is associated with the asymptotic nature of the perturbative expansions used in constructing the CW potential, that also predict $S$-matrix elements that are used to fix SMEFT Lagrangian parameters. This scale can be either suppressed or enhanced depending on the net sign of the quantum correction in the CW potential, and a suppression is consistent with an EFT analysis.

In summary, the soft breaking of the scaleless limit of the SM is such that the threshold corrections to $H^+ H$ due to integrating out the $N_p$ states can be a dominant contribution to $V_{CW}$ fixing a high scale boundary condition for the Higgs potential. This occurs for interesting parameter space when tuning of the threshold corrections against bare parameters is avoided expanding around the classically scaleless limit of the SM Lagrangian.

IV. Running down to the scale $\mu = \bar{m}_t$. We assume that the Higgs potential is (dominantly) given by Eqn. [7] when integrating out the Majorana sector. This condition can be obtained requiring (i) smaller breaking

---

1 Previous studies of the CW potential in this scaleless limit (not advocating the Neutrino Option) include Refs. [16][23]. We have introduced a hard breaking of scale invariance due to $m_q$ in Eqn. [1] If such masses were spontaneously generated the breaking of scale invariance would be completely spontaneous and introduce a dilaton [24] in the spectrum. This scenario is beyond the scope of this work. We thank D. McGady for conversations on this point.
of scale invariance in the Higgs sector and (ii) the bare tree-level Higgs potential at the scale \( m_p \) is negligible compared to the threshold contributions. The realization of these conditions in a full UV model represents a challenge alternative to the usual hierarchy problem. In such a scenario, a non-trivial consistency condition is the successful generation of the SM potential at lower energy scales and field values. The measured masses of the SM states and their couplings ensures this can occur in a very non-trivial fashion. Note also that despite the fact that the seesaw boundary condition fixes \( \lambda < 0 \), this coupling can still run to positive values at lower scales as it is not multiplicatively renormalized.

To demonstrate that a successful lower scale phenomenology can result from these seesaw boundary conditions, we take \( V_c(H^1 H) \) to be fixed to \( m^2(m_p) \equiv \Delta m^2 \) and \( \lambda(m_p) \equiv \Delta \lambda \). The parameters \( m^2 \) and \( \lambda \) are then run down according to the coupled SM RGEs. The \( \beta \)-functions for running above the top mass are introduced as \( \beta(x) = (4\pi)^2 \frac{dx}{d\ln \mu^2} \) and are taken (at leading order) from the summary in Ref. \[34\] as

\[
\beta(g_Y^2) = g_Y^2 \left( \frac{41}{6} \right), \quad \beta(g_2^2) = g_2^2 (-\frac{19}{6}), \quad \beta(g_3^2) = g_3^2 (-7),
\]

\[
\beta(\lambda) = \left[ \lambda \left( 12\lambda + 6Y_t^2 - \frac{9}{10} g_2^2 + \frac{5 g_Y^2}{3} \right) \right]
- 3Y_t^4 + \frac{9}{16} g_2^4 + \frac{3}{16 g_2^2} + \frac{3}{8 g_Y^2} g_2^2 ,
\]

\[
\beta(m^2) = m^2 \left[ 6\lambda + 3Y_t^2 - \frac{9}{20} (5 g_2^2 + \frac{5 g_Y^2}{3}) \right],
\]

\[
\beta(Y_t^2) = Y_t^2 \left[ \frac{9}{2} Y_t^2 - 8 g_2^2 - \frac{9}{4} g_Y^2 - \frac{17}{12} g_2^2 \right].
\]

Here \( g_2, g_3 \) are the coupling constants of the SU(2)\(_L\) and SU(3)\(_c\) gauge groups, while \( g_Y \) is the coupling of the U(1)\(_Y\) group. \( Y_t = \sqrt{2} m_t / v \) is the Yukawa coupling of a fermion to the Higgs with \( v^2 = 1/\sqrt{2} G_F \). Contributions proportional to \( Y_b^2 \) and \( Y_{Y_t}^2 \) have been neglected. The differential system is solved by fixing the boundary conditions to be

\[
\lambda(m_p) = -n^2 \frac{5}{64 \pi^2} |\omega|^4, \quad m^2(m_p) = \frac{n |\omega|^2}{8 \pi^2} m_p^2.
\]

\[
Y_t(m_t) = Y_t^{(0)} + Y_t^{(1)}(m_t) = 0.9460,
\]

\[
g_Y(m_t) = g_Y^{(0)} + g_Y^{(1)}(m_t) = 0.3668,
\]

\[
g_2(m_t) = g_2^{(0)} + g_2^{(1)}(m_t) = 0.6390,
\]

\[
g_3(m_t) = 1.1671,
\]

for different choices of \( m_p \) and \( |\omega| \) which approximate to one common universal scale and coupling in what follows. The number of heavy neutrino species has been denoted with \( n \) and fixed to \( n = 3 \). The \( x^{(0)} \) and \( x^{(1)}(\mu) \) stand for the tree and one-loop level contribution in the SM and we have denoted as hatted quantities observables inferred from measured input parameters. The analytic expressions for the tree-level definitions used are standard for the \{\hat{m}_W, \hat{m}_Z, \hat{G}_F\} input parameter set. The central values of the numerical inputs used are

\[
\{\hat{m}_W, \hat{m}_Z, \hat{m}_t, \hat{m}_h\} = \{91.1875, 80.387, 173.2, 125.09\},
\]

in GeV units, \( \hat{G}_F = 1.166378710^{-5}\text{GeV}^{-2} \) and \( \hat{\alpha}_s = 0.1185 \). The expressions for the \( x^{(1)}(\mu) \) used are summarized in Ref. \[34\]. The value indicated for the QCD coupling \( g_3 \) includes RG running at 4-loops in QCD and 2-loops in the EW interactions employing the expression as a function of \( \alpha_3(m_Z) \) and \( m_t \) as in Ref. \[34\]. The quantity \( \lambda(\mu = m_t) \) does not show significant dependence on the parameter \( |\omega| \) for any value \( |\omega| < 0.1 \) we have \( |\Delta \lambda| \lesssim 10^{-6} \), which is numerically insignificant in the running. Conversely, this quantity is quite sensitive to the scale \( m_p \) and the RGE order used. There is significant numerical sensitivity to the input parameters. In particular, the precise experimental determination of \{\hat{m}_h, \hat{m}_t\} is critical for the consistency of the scenario. We show the dependence on these inputs on the inferred scale \( m_p \) in Fig. \[2\]. This plot shows the value for \( \lambda(\hat{m}_t) \) consistent with experimental measurements is obtained for \( m_p \approx 10^{1.3} \text{PeV} \), assuming \( \hat{m}_t = 173.2 \text{GeV} \). The quantity \( m^2(\mu = \hat{m}_t) \) is sensitive to both \( m_p \) and \( |\omega| \).

\[ FIG. 2: \text{Value of the parameter } \lambda \text{ extrapolated at the scale } \mu = \hat{m}_t \text{ as a function of the heavy neutrino mass scale } m_p. \text{ The red line assumes } \hat{m}_t = 173.2 \text{ GeV. The surrounding band corresponds to varying } \hat{m}_t \text{ between 171 and 175 GeV (a 2σ error variation}\ [25]. The dashed line and surrounding band indicates the value of } \lambda(\hat{m}_t) \text{ consistent with the measured Higgs mass and its percentage error}\ [26]. \]

\[ \text{Fig. 3 shows its dependence on } |\omega| \text{ for } \hat{m}_t = 173.2 \text{ GeV. The surrounding band indicates the value of } \lambda(\hat{m}_t) \text{ consistent with the Higgs mass and its percentage error}\ [26]. } \]

\[ \text{This interesting region of parameter space in the seesaw model has been previously discussed in Ref.}\ [27]. \]
This translates into a constraint of
\[
\frac{3\sqrt{3}}{8\pi} \frac{|\omega|^2}{G_F \sqrt{\Delta m^2}} \lesssim 0.23 \text{ eV}, \quad 95\% \text{ C.L.,}
\] (17)
which is shown as a grey exclusion region on Fig. 3.

The overall neutrino mass scale predicted is very sensitive to the uncertainty on \(\hat{m}_t\), the chosen order of RGEs, and threshold loop corrections included in the numerical simulation. In Fig. 3 we show the absolute neutrino mass scales (grey lines) predicted at leading order as \(m_\nu = \sqrt{\omega} \nu^4\). One expects \(m_\nu \gtrsim \Delta m^2_{21}, \Delta m^2_{31}\) to avoid fine tuning and a requirement of further model building in the Majorana sector.

In addition, a negative sign for \(\lambda\) and \(m^2\) indicates a theory with a Hamiltonian unbounded from below. However, the corresponding decay time for the EW vacuum is exponentially small \([30–33]\). We have checked that the EW vacuum decays in this scenario are well approximated by the (negligible) result in the SM in Ref. [34]. The ratio of the scales at which \(\beta(\lambda)\) vanishes in the SM, compared to the SM extension considered in this paper, (which fixes the size of the action of the bounce) is \(\sim 1.00011\). The extrapolation of the theory far above the scale \(m_p\) is associated with a large theory uncertainty as the \(N_p\) could be embedded in an extended Majorana sector, with other states that can also modify the running of the couplings above the scale \(\mu \approx m_p\).

VI. Numerical stability of the results. The results shown in Section IV are produced with one loop matching conditions and one loop RGEs. Increasing the RGE and threshold matching order used shows significant numerical sensitivity. This is essentially because the coupling \(\lambda\) is running to small and negative values asymptotically which introduces a sensitivity to the scale \(m_p\), where the seesaw boundary conditions are matched. This feeds into the required \(|\omega|\) to produce the Higgs potential and EW scale, and subsequently the neutrino mass scale. For this reason, the minimal scenario is falsifiable. On the other hand, the uncertainty in \(\hat{m}_t\) is significant. To illustrate this we show in Fig. 5 the best fit points for the cases where the boundary conditions of the scenario are evolved with one loop SM RGEs, two loop SM RGEs, and one loop RGEs for \(\Delta m\) and \(\lambda\) and two loop RGEs for the remaining SM parameters.\(^3\) This last case is shown as these parameters do not have a tree level matching coefficient in this scenario. Despite this, we have confirmed that using one loop or two loop RGE’s the measured neutrino mass differences can be reproduced, see Section VIII.

\(^3\) Formally the running should be described using the SMEFT RGEs which include the effect of higher dimensional operators feeding into the running of the SM couplings [29]. We have checked that this effect is numerically sub-dominant in this model and neglected it.
The measured mass differences for the neutrino masses accommodate these observations. Potential in the minimal seesaw model with a PeV mass of SM parameters with one, two loop, or mixed RGEs for quark mass, which has been chosen to be its 2 error bars showing the experimental uncertainty in the top three RGE cases. Nevertheless, we have determined that the measured as Γ examined in the literature. We agree with Refs. [40–11] in a normal hierarchy can be obtained e.g. for \( m_1, m_2, m_3 \) = \{23.96, 24.77, 25.27\} PeV, \( \omega_0 = 10^{-4.4}, \delta \omega_{11} = 4.08 \cdot 10^{-10}, \delta \omega_{22} = -1.88 \cdot 10^{-8} \) and \( \delta \omega_{33} = -7.67 \cdot 10^{-9} \). Only the diagonal terms in \( \omega \) were used in this example leading to \( U_\nu = \text{diag}\{1,1,1\} \). The results can be perturbed by the free off diagonal entries that can combine with the unixed charged lepton mass matrix rotation matrix \( U_t \) so that \( U_t^\dagger U_\nu = U_{PMNS} \).

IX. Conclusions. Due to a non-trivial interplay of the couplings of the SM and the mass scales of the SM states expanded around the classically scaleless limit, the minimal seesaw scenario can form a UV boundary condition that induces the Higgs potential at lower energies. This can occur as a simple mechanism to generate neutrino masses is introduced extending the SM.

In this scenario the EW scale is not fundamental but is due to the quantum threshold corrections matching the heavy singlet states onto the SMEFT, which is assumed to be expanded in its near scaleless limit. Instead of an expectation of new states at the TeV scale, the multi-PeV scale is the locus of a requirement of a mass generating mechanism for Majorana states, and possibly accompanying stabilizing symmetries such as supersymmetry. This change in perspective on the hierarchy problem is possibly valuable. The key point underlying this approach is to abandon attempts to stabilise the Higgs potential at lower energies. This can occur as a simple mechanism to generate neutrino masses is introduced extending the SM.

The possibility that the \( N_\nu \) states can be viable dark matter candidates to induce the IceCube events has been examined in the literature. We agree with Refs. [40–42] that the required coupling for the event rate scales as \( \Gamma_{\text{events}} \sim (|\omega|/10^{-29})^2 (m_p/1.2\text{PeV})/\text{year} \) which is inconsistent with the preferred \( |\omega| \) to generate the Higgs potential in the minimal seesaw model with a PeV Majorana sector. Extended model building can possibly accommodate these observations.

VIII. Neutrino mass differences and mixing. The measured mass differences for the neutrino masses are given as [25]

\[
\Delta m^2_{21}/10^{-5}\text{eV}^2 = 6.93 - 7.97, \tag{18}
\]

\[
\Delta m^2/10^{-3}\text{eV}^2 = 2.37 - 2.63 (2.33 - 2.60) \tag{19}
\]

using PDG notation. Here the quoted range is \( 3\sigma \) and the brackets indicate an inverted \( m_\nu \) hierarchy. In our simple approximation of a common universal scale and coupling for the \( N_\nu \) states integrated out, we do not predict mass differences of the \( m_\nu \) or mixing angles. Treating \( N_\nu, \omega \) and the charged lepton Yukawa \( Y_\ell \) as non-degenerate enlarges the number of free parameters (15 moduli + 6 phases) to a set larger than that of the experimental constraints (2 Higgs parameters + 2 \( \nu \) mass differences + 3 PMNS angles). As an existence proof, consider \( \omega \equiv \omega_0 I + \delta \omega \) with \( (\delta \omega)_{ij} \ll \omega_0 \). Correct values for \( m^2(\tilde{m}_i), \lambda(\tilde{m}_i), \Delta m^2_{12} \) and \( \Delta m^2 \) (see Ref. [25]) in a normal hierarchy can be obtained e.g. for \( \{m_1, m_2, m_3\} = \{23.96, 24.77, 25.27\} \) PeV, \( \omega_0 = 10^{-4.4}, \delta \omega_{11} = 4.08 \cdot 10^{-10}, \delta \omega_{22} = -1.88 \cdot 10^{-8} \) and \( \delta \omega_{33} = -7.67 \cdot 10^{-9} \). Only the diagonal terms in \( \omega \) were used in this example leading to \( U_\nu = \text{diag}\{1,1,1\} \). The results can be perturbed by the free off diagonal entries that can combine with the unixed charged lepton mass matrix rotation matrix \( U_t \) so that \( U_t^\dagger U_\nu = U_{PMNS} \).

IX. Conclusions.
