Introduction

In light sources, damping rings, and in the SSC understanding non-linear aperture limits for successful cost-effective designs is becoming even more important. SSC injection requires $10^7$ turns, and beams collide for $10^6$ turns. Ideally one would like to know the dynamic aperture for this number of turns, how it depends on tune modulations, and how sensitive it could be to "unknown or omitted physics" or choice of model for the lattice.

The major obstacle to finding long-term stability limits is the fact that, tracking 1 to 64 particles through the SSC lattice for $10^4$ turns requires 500 hours of CPU time on the CRAY XMP. We have been pursuing a two pronged approach to overcoming this obstacle:

i) looking for "early warning" signs that a particle is long-term unstable, and

ii) creating maps that reproduce element-by-element tracking with sufficient accuracy and can be evaluated faster.

The goal in i) above is to detect potential long-term instability in $10^4$ turns, and the goal in ii) is to gain a factor of 30 in tracking speed. Together this would allow determination of long-term stability for 64 particles in 1 CRAY CPU minute. In this paper we discuss approach i).

There are two ways that have been suggested to look for signs of long-term instability. They both rest on the belief that if a particle is long-term unstable, it will experience a significant and discernible amount of chaotic motion. This chaotic motion may be detected by

a) looking for small departure from regular motion such as a slow change of an action invariant, or

b) tracking two neighboring particles, and looking for an exponential growth of their phase space separation.

This paper describes efforts of type a) above, and presents some recent comparisons with procedures of type b).

The rms beam radius in the SSC at injection is about 0.6 mm measured where $p_x = p_y = 370$ m. The dynamic aperture\(^1\) for 400 turn particle loss occurs at approximately $x = y = 8$ mm, and the so-called linear aperture, where $\text{rms } x$-smear = $y$ - smeared = 6.4%, occurs at about $x = y = 6$ mm (initial $p_x = p_y = 0$ always).

In Figure 1 we show the linear Courant-Snyder invariant for 400 turns at $x = y = 6$ mm. The action $J = \text{amplitude}^2/2$ plotted here exhibits an rms variation of about 12%. Using normal form techniques and differential algebra methods described in reference 2, we can find higher order invariants. In Figure 2 we plot a graph of the sixth order invariant for this same case. The rms variation of this invariant is about a factor of 10 smaller than the linear invariant.

Figure 3 shows this same 6th order invariant plotted for 10,000 turns. On this time scale the invariant exhibits large periodic swings, and we suspect the presence of a nearby synchrotron resonance. Figure 4, a phase plot of amplitude versus phase angle ($\phi_x - \phi_y - 3\phi_v$) for several initial amplitudes, confirms the presence of a large fifth-order resonance. Changing the cavity voltage so as to move off this resonance, we arrive at the results plotted in Figure 5.

What change of amplitude is acceptable on a $10^4$ turn time scale? It is not possible to answer this question in an absolute way, but the following argument suggests an order of magnitude guideline. If as a result of chaos, there is a random component to the change in amplitude of $\Delta a(t)$ for each turn, then after $N$ turns the expected change in amplitude would be $\Delta a(N) = \sqrt{N} \Delta a(1)$, and it follows in particular that

$$\Delta a(10^5) = 10^2 \Delta a(1^4)$$

If we require (arbitrarily) that $\Delta a(10^5) \leq$ the rms beam radius, then we find

$$\frac{\Delta a(10^5)}{\alpha} \leq 10^{-3}$$  \hspace{1cm} (1)

for amplitudes $\alpha$ that are about ten beam radii. As a result of these considerations we suggest using criteria (1) as a working definition of a long-term stability aperture. We have called it previously the "diffusive dynamic aperture." Here a particle is within the "diffusive dynamic aperture (DDA)" if it, and all particles of lesser amplitude, satisfy equation (1).

Returning to Figure 6 we see that the particle at amplitudes $\leq 5.4$ are within the DDA, particles at amplitudes $\geq 6.0$ are outside of this aperture. In Figure 7 we show these results extended for $10^5$ turns.
We are aware that the long term changes in amplitude can arise from sources other than chaotic motion. However, it is our opinion that it provides a margin of safety to reject such motion as unacceptable, even if its source is not from chaos. It is our opinion that significant long-term motion, on a time scale of \(10^4\) turns, is potentially hazardous, and should be avoided.

In Figures 8, 9, and 10 we show a plot of phase space separation for two particles started at the same amplitude, separated only by one part in \(10^9\). F. Schmidt has studied the behavior of such particle pairs in reference (4). According to his experience and criteria, particles at 5.4 and 6.0 mm are stable, the particle at 6.6 mm is unstable. This agrees with our determination.
