Abstract

We study the blowing-up of the four-dimensional $Z_3$ orientifold of Angelantonj, Bianchi, Pradisi, Sagnotti and Stanev (ABPSS) by giving nonzero vacuum expectation values (VEV's) to the twisted sector moduli blowing-up modes. The blowing-up procedure induces a Fayet-Iliopoulos (FI) term for the "anomalous" $U(1)$, whose magnitude depends linearly on the VEV's of the blowing-up modes. To preserve the $N = 1$ supersymmetry, non-Abelian matter fields are forced to acquire nonzero VEV's, thus breaking (some of) the non-Abelian gauge structure and decoupling some of the matter fields. We determine the form of the FI term, construct explicit examples of (non-Abelian) D and F directions, and determine the surviving gauge groups of the restabilized vacua. We also determine the mass spectra, for which the restabilization reduces the number of families.
I. INTRODUCTION

With the advent of the duality symmetries of M-theory \[1\], a new domain of string vacua (previously considered as strongly coupled) have become accessible for study. Such dual four-dimensional string vacua with $N = 1$ supersymmetry should provide a fruitful domain for studying novel phenomenological implications of string theory. In particular, the Type I string orientifolds \[2,3\] provide a promising set of new string vacua, where the techniques of the open-string theory allow for a quantitative study of the gauge structure, mass spectrum and (certain) couplings in the effective theory. The four-dimensional orientifolds \[2,3\] with $N = 1$ supersymmetry are thus particularly well suited for phenomenological studies.

One of the interesting features of the $N = 1$ orientifolds is that in general they contain a set of anomalous $U(1)$'s and the breaking of these $U(1)$'s is inherently related to the blowing-up procedure. The massless chiral superfields, formed from the Neveu-Schwarz-Neveu-Schwarz (NS-NS) and Ramond-Ramond (R-R) fields appearing in the twisted sector of type IIA orientifolds, are blowing-up moduli whose nonzero vacuum expectation values (VEV's) correspond to the geometric smoothing-out (blowing-up) of the orientifold singularities. These fields play an instrumental role in the cancellation \[3,4\] of the triangular gauge anomaly via the Green-Schwarz mechanism. In addition, their coupling to the gauge superfields \[5\] contributes to the D term of the anomalous $U(1)$, and its structure is fixed by the anomaly cancellation constraints. Thus, the Fayet-Iliopoulos (FI) term is induced when the blowing-up modes acquire nonzero VEV's. To maintain the anomalous $U(1)$ D atness of the blown-up orientifold, additional matter fields in the theory have to acquire nonzero VEV's subject to the constraint that the F atness and the D atness of the rest of the gauge sector is maintained. The generic effect of the blowing-up procedure and subsequent vacuum stabilization is then the spontaneous breaking of the gauge symmetry as well as the decoupling of a number of matter fields in the effective theory. In particular, the number of families in the effective theory may be reduced.

It is instructive to contrast the blowing-up and the accompanying vacuum stabilization of Type I orientifolds with the blowing-up of perturbative heterotic string orbifolds. There, the blowing-up of the orbifold singularities \[6\] and the stabilization of vacuum due to the anomalous $U(1)$ \[7\] are somewhat disconnected and the two procedures are different: those on the Type I side. For the $(2;2)$ orbifolds, i.e., those with the spin and gauge connection identified (analogous such constructions on the Type I side are nonexistent), there is no anomalous $U(1)$ and the blowing-up modes (twisted sector moduli) are charged under the enhanced gauge symmetry that commutes with the discrete gauge connection \[8\]. (This is in contrast to those of the Type I orientifolds which are total singularities.) Their nonzero VEV's fully break the enhanced gauge symmetry that at the orbifold limit commutes with the discrete spin connection and decouples some matter states; the procedure geometrically corresponds to blowing-up the orbifold singularities producing a smooth $(2;2)$ Calabi-Yau three-folds \[9\]. On the other hand (asymmetric orbifold and free fermionic constructions with only $(0;2)$ worksheet symmetry in general possess an anomalous $U(1)$. In contrast with the Type I orientifolds such perturbative heterotic string vacua have only one anomalous $U(1)$, whose anomaly cancellation is ensured by an universal Green-Schwarz mechanism, due to an effective Chern-Simons (CS) term, at the genus-one level, of the untwisted sector two-form field to the gauge field strength \[10\]. The
dual of this antisymmetric \text{eld}-\text{axion}, along with the (untwisted sector) dilaton \text{eld}, form a scalar component of the chiral super \text{eld}, which couples universally to the gauge sector of the theory. By supersymmetry the CS term is accompanied by a FI term (also at the genus-one level), which is proportional to the nonzero VEV of the dilaton \text{eld}. Since this VEV determines the strength of the gauge coupling and thus it is necessarily nonzero, these vacua necessarily have nonzero FI terms. The structure of this FI term is universal; it is completely fixed by the VEV of the dilaton and the trace of the anomalous $U(1)$ charges. Therefore the existence of anomalous $U(1)$ necessarily triggers the vacuum restabilization. For recent work on the systematic classification of adi directions for a set of perturbative heterotic string vacua see, e.g., Refs. \cite{16,17}.

The crucial difference in the case of the Type I orientifolds is that the blowing-up procedure and the restabilization of vacuum are now inherently connected. Since in general there are more than one anomalous $U(1)$ the anomaly associated with each is cancelled by non-universal Green-Schwarz terms, which arise due to the CS coupling of the gauge \text{eld} strengths to the twisted sector $R\cdot R$ two-form \text{elds} (which is dual to the twisted sector $R\cdot R$ scalars \text{axions}). Thus each of the anomalous gauge group factors has a cancellation ensured by a specific combination of twisted sector $R\cdot R$ axions. The non-universality of the Green-Schwarz mechanism via twisted $R\cdot R$ sector axions is generic in $N=1$ orientifolds constructions. Due to supersymmetry, these CS terms are accompanied by the corresponding FI terms, which involve a specific combination of the twisted sector $NS\cdot NS$ \text{elds}\text{\textbackslash{}\texttextbackslash{}blowing-up modes}. Consequently, when these twisted sector dilatons acquire nonzero VEVs, the orbifold singularity, associated with particular \text{xed} points where the D branes are located, is blown-up. This procedure in turn induces non-universal FI terms, which for each anomalous $U(1)$ is proportional to a specific combination of the VEVs of the blowing-up modes. The appearance of FI term then triggers the vacuum restabilization.

The purpose of the present paper is to explore in a concrete way the effects of the blowing-up procedure for four-dimensional $N=1$ orientifolds. The explicit vacuum restabilization triggered by the blowing-up has to be carried out, and the surviving gauge structure and light mass spectrum determined before phenomenological implications of the blown-up orientifolds can be addressed. The goal is to carry out this procedure explicitly for specific blown-up orientifolds and to study its consequences. (Unlike the four-dimensional $N=1$ orientifolds, the blowing-up procedure of six-dimensional $N=1$ orientifolds is better understood and related geometrically to blowing-up of the ADE singularities of K3 surfaces.)

While by now a large class of $N=1$ orientifolds have been constructed \cite{34}, only specific models (usually with additional Wilson lines included) contain matter \text{elds} which are non-Abelian singlets. These singlets could be candidates for the restabilization of the blown-up orientifold vacua, since in such cases it should be possible to achieve a systematic classification of adi directions, very much along the lines developed for vacuum restabilization of the perturbative heterotic string vacua via non-Abelian singlets \cite{16,17}.

On the other hand, a large class of (simpler) Type I orientifold constructions have no

\footnote{It is commented that at the orientifold limit there is no genus-one correction to the FI term, calculated for the ABPSS orientifold model in Ref. \cite{20}.}
non-Abelian gauge singlets, and thus the vacuum restabilization of the blown-up orientifold should necessarily proceed by giving VEV's to non-Abelian matter fields. In this case the classification of D at directions is complicated by non-Abelian D atness constraints, and a systematic approach to the study of vacuum restabilization is lacking. Nevertheless, the powerful connection between the holomorphic gauge-invariant monomials and the D at directions \[21\] (which generalizes in the non-Abelian case to polynomials) facilitates the construction of non-Abelian D at directions. Applications of this approach to the vacuum restabilization of the blown-up Type I orientifolds (without gauge singlets) will be the focal point of this paper.

One of the immediate consequences of the vacuum restabilization with non-Abelian fields is the breaking of the large non-Abelian gauge groups down to smaller ones. From the phenomenological point of view, the vacuum restabilization of the blown-up orientifold is one of a few ways to achieve smaller gauge groups with reduced massless particle content. In that sense, it could be viewed as complementary to other "stringy" methods in orientifold construction, which involve splitting the 32 nine- (or ve-) branes among different fixed points of the orbifold, turning on the background NS-NS antisymmetric B-field, adding discrete Wilson lines (see e.g., \[4\]), etc.

The paper is organized in the following way. In section II we describe the spectra and the superpotential of the first four-dimensional orientifold with N = 1 supersymmetry, constructed by Angelantonj, Bianchi, Pradisi, Sagnotti and Stanev (ABPSS orientifold) \[4\]. We discuss the general procedure of anomaly cancellation and the generation of FI terms and explicitly write down the FI term for the anomalous U(1) of the ABPSS model. In section III, we discuss the atness conditions of the model in the restabilized vacuum and the method of classifying the D at directions. In section IV, we present classes of D at directions that are also FI at to all orders, and discuss the consequences of the restabilized vacuum. In section V, we present the conclusions.

II. ABPSS MODEL AND ANOMALY CANCELLATION

A. Massless spectrum and superpotential couplings of the ABPSS orientifold

We choose to analyze the ABPSS model. This is a Z3 orientifold with the gauge structure:

\[
\text{SO}(8) \quad \text{SU}(12) \quad \text{U}(1)
\]

and a matter content of three copies of

\[
(8;12)_1 \quad (1;66)_2 \quad 1;2;3;
\]

which arise from the open-string sector, due to the strings stretching between the nine-branes located at the orientifold singularities.

In the Type IIB orientifold (closed string) sector, in the NS-NS sector there is the gravity supermultiplet and the 36 (chiral) supermultiplets corresponding to the 9 untwisted ("toroidal") and 27 twisted (blowing-up) sector moduli. The moduli are total gauge singlets (unlike the twisted sector moduli of the perturbative heterotic orbifolds), whose real and
imaginary components arise from the NS-NS and R-R sector, respectively. In particular, the ABPSS orientifold has the untwisted sector dilaton $S$, moduli singlets $T_i$ ($i = 1; \ldots; 9$) and 27 twisted sector supermultiplets, out of which only one participates in the blow-up procedure, since all the nine-branes are sitting at the fixed point of the $\mathbb{Z}_3$ orbifold at the origin. The twisted sectors ($k = 1;2$) give the NS-NS 2-forms and the R-R two-form 2-forms $C_k^{(2)}$ (which by duality are related to the twisted sector R-R axions $a_k$). They are constrained by the reality condition $1 = 2; C_1^{(2)} = C_2^{(2)}$. In addition, the orientifold projection removes the real components of $k$ and $C_k^{(2)}$.

The renormalizable superpotential is of the form

$$W_3 = y a_i b_i \varepsilon_{i\mu\nu};$$

where $y$ is a constant; $\varepsilon$ are family indices; $i$ is an SO (8) index; and $a,b$ are SU (12) indices.

In the following we shall address the nature of Chern-Simons (CS) terms in orientifold models and derive the explicit expressions for the case of the ABPSS orientifold.

B. Chern-Simons terms, Fayet-Iliopoulos terms, and anomaly cancellation

The $U$ (1) triangular gauge anomalies are cancelled via the Green-Schwarz mechanism involving the exchange of twisted sector R-R 2-forms $a_k$ (twisted axions) due to the CS couplings [18]. For the four-dimensional Type I orientifold the coupling takes the form:

$$I_{CS} = \sum_{k} \mathbb{Z} d^4 x C_k^{(2)} e^F = \sum_{k} \mathbb{Z} d^4 x C_k^{(2)} \text{Tr}(a_k) F + \cdots;$$

where $C_k^{(2)}$ is the R-R 2-form in the $k$th twisted sector; their duals are the scalar fields $a_k$. $F$ schematically represents the gauge field strength of the anomalous $U$ (1), associated with the D-brane located at the orientifold singularity. The matrix $a_k$ describes the action of the orbifold group on the Chan-Paton (CP) factors in the $k$th twisted sector. For the $\mathbb{Z}_N$ orientifold, it takes the form $a_k = e^{i2\pi kV;H}$ in the Cartan-Weyl basis, where $V$ is a 16-dimensional real vector and $H$, ($I = 1; \ldots; 16$) are the Cartan generators of SO (32) represented by tensor products of 2 $\mathbb{Z}_3$ submatrices. For the sake of simplicity we concentrate ourselves to the case of 32 branes of the same type located at a single fixed point.

The supersymmetric completion of the first term in eqn. (2) gives the Fayet-Iliopoulos (FI) contribution to the action:

$$I_{FI} = \sum_{k} \mathbb{Z} d^4 x \text{Tr}(a_k) D;$$

where $D$ is the auxiliary component of the vector multiplet which contains the gauge field $A$ of the anomalous $U$ (1). Hence, the FI term is given by

$$I_{FI} = \sum_{k} \mathbb{Z} \text{Tr}(a_k) D;$$

5
where the sum is over twisted sectors, is the Chan-Paton matrix associated with the gauge boson of the anomalous U(1). In the Cartan-Weyl basis, it takes the form \( q_{ij} = H \), where \( Q_1 \) is a 16-dimensional real vector. For the \( Z_N \) orientifold, the spectrum of the \( k \)-th twisted sector and the \( (N-k) \)-th twisted sector satisfy reality conditions, e.g., \( k = \frac{N}{2} \) and \( C^p_k = C^p_{N-k} \). Furthermore, the orientifold projection projects out the real components of \( k \) and \( C^p_k \) (see e.g. [22]). In addition, the action of the orbifold group on the Chan-Paton indices has the following property:

\[
Tr(k) = [Tr(\alpha k)].
\]

Then the FI term takes the form:

\[
F_I = 2 \text{Re}(Tr(x)) = 2 \text{Im}[Tr(x)] \text{Im}(k):
\]

Note that due to the reality constraint, the sum is only over the first half of the twisted sectors.

A similar argument applies to the coupling between the twisted sector \( R-R \) scalar field \( \kappa \) and the gauge field \( A \), thus yielding the CS coupling of the type:

\[
Z \int d^4x \text{Im}[Tr(x)] \text{Im}(k)A:
\]

Thus the imaginary components of \( k \) and \( \kappa \) can be combined into the physical moduli \( R_k \) of the \( Z_N \), \( R_k = \text{Im}(k) + i\text{Im}(k) \) in which \( k \) goes from 1 to \( \frac{N}{2} \).

For \( Z_3 \) orientifold models, which have two twisted sectors, the reality condition on the twisted sector NS-NS scalars reduces to \( k = 2 \) and the FI term (8) then takes the form:

\[
F_I = 2\text{Im}[Tr(x)]\text{Im}(1):
\]

The physical moduli of the \( Z_3 \) of the single twisted sector is \( R = \text{Im}(1) + i\text{Im}(1) \).

A few comments are in order regarding the units appearing in front of the CS term. The nine-brane CS term in 10 dimensions has dimension one; it is proportional to \( \text{Def}_{10} = 1 \). Dimensionally reducing such a term to four-dimensional effective theory, the prefactor gains a volume factor \( V_6^{1/4} \frac{1}{q_4} = \frac{1}{4} \). With the convention of assigning VEV’s of \( R \) in terms of dimensionless quantities (just as the convention for the dilaton field \( S \)), the prefactor of the FI term (8) is of dimension 2. However, since the CS-type couplings arise from the untwisted sector, they are absent in the four-dimensional theory of the \( N = 1 \) orientifolds. Nevertheless, we would like to argue that the dimensionful parameters of the CS term associated with the twisted sector are of the same structure. Such a term should be calculated in perturbative open-string theory by evaluating the disk diagram for two matter fields at the boundary and a twisted field \( C_k \) integrated over the bulk. While this calculation is technically involved due to subtleties of the twisted sector fields, the dimensionful parameter of the resulting term

\[\text{2A related calculation was given for six-dimen} ...\text{Appendix of [3].}\]
is expected to have the same structure as that obtained by a naive dimensional reduction. Gauge coupling corrections. Analogously, one would like to determine the correction of the twisted sector blowing-up modes to the gauge function:

\[ f = S + f(R) : \] (9)

Here \( S \) is the (untwisted sector) dilaton for the case of the nine-brane sector (it is the untwisted toroidal moduli \( T \) in the case of the five-brane sector.) The coupling of \( \text{Im} \ f(R) FF \) could in principle appear as the second order expansion of the Chern-Simons term \( \mathcal{Z}_N \). In the case of \( Z_N \) orientifold such a term takes the form:

\[ \frac{x^Z}{k} d^4x \text{Tr}( \frac{1}{k^2} ) \frac{k}{k} FF ; \] (10)

Thus when summed over the twisted sectors only the real component of \( k \) survives. However, it is projected out by the orientifold projection. Hence, the term \( \text{Im} f(R) FF \) seems to be absent, indicating that \( f(R) = 0 \), i.e., for \( Z_N \) Type I orientifolds, there seems to be no gauge coupling correction due to the twisted sector moduli. Note that in contrast to Type I orientifold, Type II \( Z_N \) orbifolds allow such terms since the real components of the twisted sector \( R-R \) fields are not projected out.

Anomaly cancellation. The symmetry factors in the string amplitudes for a disc that involves three gauge fields as external legs can be determined by identifying the effective coupling of the twisted-sector \( R-R \) fields to these gauge fields strengths as arising from the CS couplings of the type (3) (such a string diagram can then be viewed as dominated by the exchange of \( RR \) fields (7)). In principle, the pre-factors of the amplitudes can be fixed by requiring the exact cancellation of the gauge anomalies. In particular, the amplitude of the scattering of a \( U(1) \) gauge boson and two non-Abelian \( G_j \) gauge bosons with tree level exchange of a \( R-R \) scalar is (7).

---

3 In compactifications from \( D = 10 \) to \( D = 4 \), the case in which the gauge groups arise from the five-brane world-volume theory, this relationship is modified by ratios of the compacted five-brane world-volume and the volume of the bulk. However in the case of the nine-branes (which fill up the full nine-dimensional spatial part of the ten-dimensional theory), the result depends only on the volume of the six-dimensional space.

4 One resolution to this problem may have to do with modifying the prescription that the sum is done only over the first \( (N-1)=2 \) twisted sectors of the \( Z_N \) orientifold. However, this would have to be confirmed by explicit string calculations. We thank A. Uranga for communication on that point.

5 If the effective couplings between the \( R-R \) fields and two non-Abelian gauge bosons are determined from the expansion of the CS term of the type (3), and adding up the contributions from all twisted sectors, the contributions from the \( k^{th} \) and \( (N-k)^{th} \) twisted sector to such an effective term add up to zero, since the orientifold projection keeps only imaginary components of the \( C_k^{(2)} \) form s.
\[ A_{ij} = \sum_{j=1}^{P} j \int \frac{X}{C_k \text{Tr}(k_{i}) \text{Tr}(1_{j})^{2}}; \]  

(11)

where \( P \) is the order of the orientifold group and \( k \) runs over the twisted sectors. For a particular of the \( Z_N \) orbifold, \( C_k \) are given by [1]:

\[ C_k = \sum_{a=1}^{3} 2 \sin{k \nu_a}; \]  

(12)

where \( \nu_a \) is the compact space twist vector. \( A_{ij} \) cancels the usual \( \Phi \) theory triangular anomalous of the model [1].

C. Fayet-Iliopoulos term and anomaly cancellation of the ABPSS model

In the ABPSS model, the CP matrix in the Cartan-Weyl basis for the anomalous \( U(1) \) gauge field is \( \Phi \), \( \text{diag} I_{12}, I_{12}, 0, I_{8}, \) in which \( I_n \) is the \( n \) \( n \) identity matrix. The matrices are given by

\[ k = \text{diag} e^{(2 \pi i / 3)} I_{12}, e^{(2 \pi i / 3)} I_{12}, I_{8}; \]  

(13)

where, \( \frac{2}{3} \).

The FI term of the anomalous \( U(1) \), which arises from the supersymmetric completion of the Chern-Simons couplings between the twisted sector \( \Phi \) fields and the gauge fields [3], is given by eqn. (4) with \( \Phi \) and \( k \) of the ABPSS model:

\[ F_I = 2 \left( 12 \sin \left( \frac{2}{3} \right) \text{Re}(\Phi) = 2 \left( 12 \right) \left( 2 \sin \left( \frac{2}{3} \right) \text{Re}(\Phi) \right); \]  

(14)

where \( \Phi \) is the twist sector moduli field. \( F_I \) modifies the usual \( U(1) \) D term as

\[ D \equiv D + F_I; \]  

(15)

Therefore, the FI term is proportional to the VEV of the real component of the twisted moduli \( \Phi \).

The coupling of \( \text{Im} \ f(\Phi) \Phi \Phi \) in the case of ABPSS orientifold could take the form:

\[ \int \frac{X}{2} Z d^4 x \left( 1_{2} \right) \left( 1_{2} \right) \text{Tr}(k_{i}) \text{Tr}(1_{j})^{2} = 2 \left( 12 \right) \text{cos} \left( \frac{2 \pi i}{3} \right) \text{Re}(\Phi); \]  

(16)

However, the string amplitude that involves the diagram with three gauge bosons as external legs involves exchanges of \( \Phi \) fields \( k \) in each twisted sector separately. The total contributions to such a string amplitude, summing over the twisted sectors, would then yield a nonzero effective coupling that involves two non-Abelian gauge bosons and the the anomalous \( U(1) \) gauge boson, as quoted in [4].
Since the real component of $I_1$ is projected out by the orientifold projection, the term $\text{Im}(f(R)FF)$ seems to be absent (as discussed on general grounds in the previous subsections).

In the ABPSS model, the $U(1)^3$, $U(1)^{SO(8)}$, and $SU(12)^2$ anomalies are

$$\begin{align*}
(432; 36; 18);
\end{align*}$$

respectively.

Since the compact space twist vector for $Z_3$ is $v = \frac{1}{3}(1; 1; 2)$, one obtains $C_1 = C_2 = 3^3$. Thus, the scattering amplitudes $A_{ij}$, with the matrices presented previously, are [1]

$$A_{U(1); U(1)SO(8); SU(12)} = \frac{1}{3} \left( \frac{3}{2} \right) \left( \frac{3}{2} \right) \left( \frac{3}{2} \right) \left( \frac{1}{2} \right) = (432; 36; 18);$$

which cancel the $U(1)$ anomaly in eqn. [17].

### III. ANOMALOUS $U(1)$ AND VACUUM RESTABILIZATION

The appearance of the FI term for the anomalous $U(1)$ due to the blow-up procedure requires the well-known vacuum restabilization procedure to preserve supersymmetry at the string scale. Certain fields that are charged under the anomalous $U(1)$ are triggered to acquire nonzero vacuum expectation values (VEVs) that cancel the FI term, subject to the constraints that they are both $D$ at with respect to the other gauge groups and $F$ at, leading to a consistent "restabilized" string vacuum. As a consequence, some fields become massive (depending on the size of the FI term, which generally sets the scale of the VEV’s, they will either decouple or remain in the low energy theory). In addition, the rank of the gauge group is usually reduced as well as the number of families.

In previous work [16], techniques were developed to construct the moduli space of the at directions for models with an anomalous $U(1)$ systematically. The method utilizes the one to one correspondence of $D$ at directions (under both the non-anomalous Abelian gauge groups and the non-Abelian gauge groups) with holomorphic gauge-invariant polynomials built out of the chiral fields in the model. For simplicity, the at direction analysis in [16] considered only the non-Abelian singlet fields in the model, in which case the at directions correspond to monomials ($\text{HM}$’s). In particular, the superbasis, which is the set of the one-dimensional (i.e., that depend on one free VEV) $\text{HM}$’s of the model, can be constructed. Every $D$ at direction can be expressed as a product of the elements in the superbasis, such that the positivity of the VEV-squares of the fields can be satisfied automatically. For example, if the $i^{th}$ $\text{HM}$ for the at direction is $P_i = \prod_{p} n_{p}^{i}$, then the fields $p$ have VEV’s

$$\mathbf{h}_{p|ij} = \prod_{1}^{X} n_{p}^{i} w_{ij};$$

where $v_{1}$ is the VEV corresponding to $P_1$. The phase of the $\mathbf{h}_{p|ij}$ can be chosen for convenience.
The HIM's of the superbasis are then classified according to the sign of their contribution to $D_A$, the D term of the anomalous U(1). Since the FI term for the anomalous U(1) has to be cancelled by the VEV's of certain fields in the model, the sign of the FI term is crucial. To ensure the $D_A$ invariance constraint, the required HIM's should necessarily contain one or more elements that are in opposite sign to that of $F_I$.

The constraints of $F_A$ invariance require that $hSW = 0$ for all of the massless superfields in the model. Further consideration of these conditions demonstrates that there are two types of dangerous terms which can lift a given D at direction. The first class of terms, which we denote as the $W_A$ terms, are formed solely of the fields that are in the D at direction. Gauge invariance dictates that if such a term can be constructed, it can appear in the superpotential raised to any positive power. In this case, for the D at direction to remain F at all orderings in the superpotential, string selection rules must conspire to forbid the existence of a term $W_A$ term which can be difficult to prove in general. We choose to adopt a conservative strategy and do not consider D at directions for which $W_A$ terms can appear (with the recognition that in doing so, we may be neglecting possible at directions which are in fact F at all orderings).

The other type of dangerous term $s$, which we denote as the $W_B$ terms, are linear in an additional massless superfield which is not in the at direction (i.e., which has zero VEV), such that $hSW = 0$ but $hSW = 0$ if $i$ may be nonzero. In this case, gauge invariance constrains the number of $W_B$ terms $s$ to be finite, and an explicit string calculation can be performed to determine if such terms are in fact present in the superpotential. Thus, the at direction can be shown to be F at all orderings if all such $W_B$ terms vanish. It is also possible that in certain cases the contributions to the F term $W = 0$ from different $W_B$ terms $s$ linear in the same field (which is not in the at direction) could be arranged to cancel for appropriate magnitudes and signs of the VEV's of the fields involved.

In the present model, the D at directions necessarily involve non-Abelian fields due to the matter content. In principle, the problem could be simplified significantly if only one component for each superfield which is charged under SU(12) and/or SO(8) is nonzero, such that only diagonal generators would be involved in D at directions for the non-Abelian gauge groups. In this case, however, the problem is similar to that of the Abelian case (Abelian-like), and the techniques developed in [14] and described above can be directly applied.

The one to one correspondence between holomorphic gauge invariant polynomials (HIP's) and non-anomalous D at directions [21] provides a powerful way of searching for a more general class of D at directions with non-Abelian fields. We first construct a gauge invariant polynomial from the non-Abelian fields, which is a sum of monomials involving the components of the fields. Then one monomial term defines a D at direction. Each monomial in the polynomial will have the same magnitude of the VEV (or times $\frac{P}{n_p}$ if the component field is raised to the $n_p$ power). The D at invariance constraints for both diagonal and o-diagonal generators of the non-Abelian gauge group are automatically satisfied. Other at directions are gauge rotations of the direction corresponding to a single monomial. They are equivalent to a product of monomials from the same HIP. Each monomial introduces the same magnitude of the VEV for each component present (or $\frac{P}{n_p}$), but the phases of the VEV's are dictated by the gauge rotation.

One can also consider higher dimensional D at directions (with more than one independent VEV), formed as products of other HIP's. The at directions correspond to products...
of monomials from each of the HIP's, each with its own VEV. Such products often have a reduced surviving gauge symmetry and massless particle content. They are sometimes F at (due to cancellations) for specific ratios of the VEV's and choices of phases, even though the directions corresponding to a single HIP are not. For overlapping polynomials, which are products involving common multiplets, there is a direction in which the common multiplets have the same nonzero component (or involve components not connected by any single gauge generator) for each of the monomial factors, which avoids non-zero D terms for o-diagonal generators. The VEV's of the nonzero components in a product are given by an expression analogous to (13). For products of non-overlapping HIP's (i.e., with no multiplets in common), the corresponding monomials may have different orientations in the internal symmetry space.

IV. FLAT DIRECTIONS

The F atness conditions of the ABPSS model are
\[ i^a a^b_i = 0; \]  
\[ i^b b^a_{[a,b]} = 0; \]  
where \( T^I \) are generators of the vector representation of SO (8) and \( I = 1; \ldots; 28 \). For SU (12),
\[ D^J = X^{\mu \nu}_{i a b} T^J_{\mu a \nu b} I^a_i + X^{\mu \nu}_{a b} T^J_{\mu a \nu b} I^a_i \]  
where \( T^J \) are the generator matrices for the fundamental (anti-fundamental) representation of SU (12) and \( J = 1; \ldots; 143 \). The D atness condition for the anomalous U (1) is given by
\[ D_A = X^{\mu \nu}_{I a} I^a_i + 2 X^{\mu \nu}_{[a,b]} I^a_i + F \]  
Since there are no non-Abelian singlet fields in the model, the D at directions are necessarily formed of super fields which transform non-trivially under the non-Abelian gauge groups. Due to the form of the superpotential and the number of families, we have not been able to construct a D at direction involving only one component per multiplet, namely, the Abelian-like solution with only the diagonal generators of SU (12) involved.

\[ ^G \text{Gauge or family rotations of that at direction may have additional nonzero components of the same multiplets. The D atness of the o-diagonal generators then occurs by cancellations.} \]
We thus concentrate on the holomorphic gauge invariant polynomial method as a more general and powerful tool. We construct gauge invariant (under SO(8) \( \times SU(12) \)) combinations of fermions \((a, b)\). Any monomial from the Higgs involving particular components of the fermions and/or \((a, b)\) is a one-dimensional \( D \) at direction. Other \( D \) at directions can be constructed from products of these one-dimensional directions. We then check the F-term constraints.

We have found classes of \( D \) at directions involving only, exploiting the fact that the totally antisymmetric product \((a, b, c)\) is an SU(12) singlet. Different combinations of the family indices for the six \((a, b, c)\) or products of such polynomials correspond to different residual symmetries and spectra after vacuum stabilization. The \((a, b, c)\) have U(1) charges +2, so that these \( D \) at directions have \( D_A = 0 \) for \( \text{Re}(R) < 0 \), i.e., for positive \( \text{Re}(R) \) in (14). The VEV's of the components of the \((a, b, c)\) are proportional to \( \text{Re}(R) \), so they interpolate smoothly to the limit \( \text{Re}(R) = 0 \).

The one-dimensional \( D \) at directions take the form (up to a gauge rotation)

\[
6 = \begin{bmatrix} 1 & 2 & 3 & 4 & 5 & 6 \end{bmatrix}^T,
\]

where the family indices \( i \) take the values 1, 2, or 3. This monomial is a singlet under SO(8), with anomalous U(1) charge +12.

In addition to SO(8), which obviously remains unbroken by this class of \( D \) at directions, the remaining unbroken gauge symmetries from SU(12) clearly contain SU(2)\(^6\), where each SU(2) corresponds to the indices of one of the \((a, b, c)\) in the \( D \) at direction. However, since there are only three possible values of the six \( i \), these are not all the unbroken generators of the original SU(12). There are additional o-diagonal generators which remain unbroken such that the remaining gauge symmetry is Sp(21) \( \times \) Sp(2m) \( \times \) Sp(2n)\(^n\), where \( l, m, n \) are the number of occurrences of the direction 1, 2, and 3, respectively, and \( 1 + m + n = 6 \). (Of course, Sp(2) \( \times \) Sp(2) \( \times \) Sp(2k) factor is absent for \( k = 0 \), where \( k = l, m, n \).

In Appendix A, an example with two \((a, b, c)\) is given to illustrate the survival of the Sp(4) gauge group.

There are also \( D \) at directions which are arbitrary superpositions of directions with different family indices but the same SU(12) indices. These are equivalent to each of the six factors having an independent direction in family space; i.e., \( a \) is promoted to a vector in the three-dimensional family space, with each component having an arbitrary phase. Thus,

\[
\begin{bmatrix} a_1 \beta_1 & a_2 \beta_2 & a_3 \beta_3 \end{bmatrix}^T \begin{bmatrix} a_1 \beta_1 & a_2 \beta_2 & a_3 \beta_3 \end{bmatrix},
\]

where \( [a_1, b_1] = [1, 2]; [3, 4]; [5, 6]; [7, 8]; [9, 10]; [11, 12] \), and the VEV's of these components in the family space satisfy

\[
J_{1, a, b, a}^I + J_{2, a, b, a}^I + J_{3, a, b, a}^I = v^I,
\]

where \( v \) is the VEV determined from \( \text{Re}(R) \). The generic residual symmetries are SU(2)\(^6\), except for the special directions for which \( k \) of the \( a \) are aligned, in which case SU(2)\(^k\) ! Sp(2k).

The space of the \( \text{Re}(R) \) is a subspace of the 366-dimensional complex space of \( \begin{bmatrix} a_1 & b_1 \end{bmatrix} \). At a generic point (the vectors \( a \) in family space are different from each other), other \( D \) at directions can be constructed by family and phase transformations.classified

---

\[\text{Note that in the orientifold limit, appearance of Sp(2k) groups is usually associated with existence of ve-branes. Interestingly, the ABPSS orientifold has only nine-branes, yet the blow-up procedure introduces Sp(2k) groups.}\]
by \(U(3)=U(2)\) for each of the six factors \(a_{i,a}^{i,1}\). One of the generators of \(U(3)=U(2)\), one is from \(SU(12)\), \(U(1)\), and the other four correspond to moduli. Hence, the generic point with 6 arbitrary \(i\) from a 12-dimensional complex moduli space. The points in moduli space that involve permutating the \(i\) and associated phases are equivalent by discrete gauge transformations, such as the one which maps \(i\) to \(\frac{1}{2}\). The spectrum for a generic point includes 126 massive states associated with the spontaneous breakdown of \(SU(12)\). \(U(1)\) to SU(2)\(^6\) (the imaginary parts are the absorbed Goldstone bosons and the real parts are the massive scalar partners). In addition, there are 3 \(SU(6)\) = 72 massless complex states, 12 of which are associated with the moduli. At the special points in the moduli space where the vectors in the family space \(i\) are aligned, the gauge symmetries are enhanced. There are correspondingly more massless states and fewer associated with symmetry breaking.

To determine the spectrum for the \(a_{i,a}^{i,1}\), consider any of the six factors of \(a_{i,a}^{i,1}\). Without loss of generality, we can choose axes in family space such that \(n\) for a specific \(i=1,2,3\), \(w\) with the other VEV's vanishing. From the superpotential

\[
W_3 = 2yv\left(\frac{a}{1} i^{a} b_{i}^{b} + \frac{a}{1} i^{a} b_{i}^{b}\right)
\]

(where \(a_{i,a}^{i,1}\) one has that \(i^{a} b_{i}^{b}\) and \(i^{a} b_{i}^{b}\) become massive (\(2yv\)), while \(i^{a} b_{i}^{b}\) remain massless. Similarly, two of the three families become massive for each of the 12 relevant values of the \(SU(12)\) index. \(SO(8)\) remains unbroken.) In the special case of \(l=m=0\), \(n=6\), for example, \(a_{i,a}^{i,1}\) \(i=1:12\) remain massive in the restabilized vacuum. Hence, three apparent families are reduced to one. This suggests that it may be worthwhile to consider models with more than three apparent families.

The \(a_{i,a}^{i,1}\) at directions are flat at all orders, since \(SO(8)\) \(U(1)\) \(i=1,2,3\) invariance requires at least two factors of for each term in the superpotential. The form of the effective superpotential (after restabilization) for the massless states depends on the specific direction. \(U(1)\) \(i=1,2,3\) invariance implies that \(n=2n\) for an allowed term in the original superpotential, where \(n\) and \(m\) are respectively the number of factors of \(i=1,2,3\). Effective cubic terms must therefore result from surviving terms in the original superpotential\(W_3\) in (1). Such terms survive for points in the moduli space except for the maximal symmetry points like \((l,m,n)= (0;0;6)\). There could conceivably be four-dimensional effective couplings from original non-renormalizable couplings of the type \(\frac{2}{1} h^{3} i\). However, these would have to be of different form than \(W_3\).

The generic \(a_{i,a}^{i,1}\) at directions that we have discussed so far are technically of the overlapping type; i.e., they involve products of monomials in which more than one component of the same \(i=1,2,3\) is allowed to have a VEV, as occurs, for example, \(i=1\) and \(i=2\), associated with \(\frac{1}{3}\) and \(\frac{2}{3}\) are not orthogonal. For this class of direction this presents no difficulty: no \(SU(12)\) generator connects \(\frac{1}{3}\) with \(\frac{2}{3}\), for example, and no diagonal couplings are induced. For this to work, it is necessary for the \(SU(12)\) indices to be the same in each monomial, i.e., each has the same \(SU(12)\) orientation.

There is another class of \(a_{i,a}^{i,1}\) at directions involving non-overlapping polynomials, such as \((\frac{1}{3})^{6}(\frac{2}{3})^{6}\), or \((\frac{1}{3})^{6}(\frac{2}{3})^{6}(\frac{3}{3})^{6}\). Since they are non-overlapping, there is no need for the \(SU(12)\) indices to be the same in each factor. These directions therefore allow even more breaking of the \(SU(12)\), although to maintain the non-overlapping character there is much
less freedom for rotations in the family indices\(^8\). There are many possibilities for the relative SU (12) orientations of the (12) factors, with different implications for the physics of the associated restabilized vacua. We will simply use two examples given in Appendix B to illustrate the complexity of the physics associated with this class of directions.

There are other classes of directions which are D at with respect to SO (8) SU (12), of the generic form \( \text{SU}(12) \) or \( \text{SU}(12) \). Such directions have negative U (1) \( A \) charges, and would yield \( D_A = 0 \) for blown-up constructions with \( F_I > 0 \). These would correspond to \( \text{Re}(R) < 0 \) in (14), and would not have a canonical geometric interpretation. For such directions, each (12) factor is totally antisymmetric in the SU (12) indices, while the SO (8) indices are contracted in pairs. The latter can be within the same \( (12) \) factor, in which case they must have different family indices, or can connect different (12) factors. However, we have not found any examples of this class which are also F at.\(^9\)

Similarly, we have not found any non-trivial solutions involving both the \( a \) and \( b \) fields in the \( a b \) direction. Clearly \( [a; b] \) is not F at, and we have not found combinations involving different families, etc., which are both F and D at.\(^10\). (Of course, the orientifold point with \( \text{Re}(R) = 0 \) has \( F_I = 0 \), and the trivial solution with no nonzero VEV is D and F at.)

V. CONCLUSIONS

The aim of this paper has been to address explicitly the blowing-up procedure of the four-dimensional Type I orientifolds with \( N = 1 \) supersymmetry. The specific analysis was done for the Type I \( Z_3 \) orientifold constructed by Angelantonj, Bianchi, Pradisi, Sagnotti and Stanev (ABPSS orientifold) \(^4\). We chose it in part due to its simplicity (it involves only nine-branes), and in part due to its potential phenomenological implications since the model contains three families. The goals were two-fold: (I) we identified the fields participating in the blowing-up procedure, and determined the structure of the induced Fayet-Iliopoulos (FI) term, and (II) we provided a detailed analysis of the at directions, surviving gauge symmetry, and light particle spectra after the subsequent vacuum restabilization of the blown-up orientifold.

\(^8\)There are also hybrid at directions, involving family rotations for some of the 12 factors and SU (12) rotations for others.

\(^9\)We have also not found any F at examples for generalizations involving overlapping polynomials in which the monomials have different combinations of SU (12), SO (8), and family indices. These generically induce D terms for the one-diagonal generators, but these can often be cancelled by appropriate choices of relative signs for the fields in a monomial.

\(^10\)In \(^4\), a form of directions involving both and which satisfied F atness was given. However, no examples which were D at were presented, nor was their existence proved. The examples presented in this paper are both D and F at, and are outside of their class. 

14
For the $Z_3$ ABPSS orientifold, only one twisted sector blowing-up mode $R$ participates in the blowing-up procedure and triggers the subsequent vacuum restabilization. It is associated with one out of the 27 wed points, chosen at the origin where the nine-branes are located. We showed that the real part $\text{Re}(R) = 0$ of this blowing-up mode (which arises in the NS-NS twisted Type IIB sector) contributes to the FI term. The nonzero vacuum expectation value (VEV) of this field, which, based on the geometrical interpretation of the blowing-up procedure, should be taken to have positive sign, $\text{Re}(R) = 0$ of the blowing-up mode (which arises from the $R$-$R$ twisted sector). We also noted that the second order expansion of this $R$-$R$ lifting term, which contributes to the imaginary part of the gauge coupling corrections, does not seem to be present (the part of the $R$-$R$ sector two-form field that would contribute to this coupling is projected out by the orientifold projection).

(II) Due to the absence of non-Abelian singlet fields in the spectrum, the subsequent vacuum restabilization necessarily involves non-Abelian fields, thus complicating the analysis. We employed the powerful connection between holomorphic gauge invariant polynomials and at directions [21], which enabled us to classify the $D$ and $F$ at directions of the blown-up orientifold in detail. We found that the $D$ and $F$ at directions of this model are associated with the general set of 6 monomials, in which transform as $(1;66)_2$ under $SO(8)$ SU(12) U(1). We were unable to find $D$ and $F$ at directions for the gauge invariant monomials of the type $^{12}_{12}$, in which transform as $(8;12)_1$ under $SO(8)$ SU(12) U(1). We were also unable to find hybrid directions with both the and fields involved. Incidentally, only the 6 $D$ at directions of this model have the correct sign of the $U(1)$ charges to cancel the FI term with the positive value of the blowing-up mode.

The generic point in the moduli space of $D$ and $F$ at directions associated with the 6 monomials is specified by 12 complex moduli (fields that acquire free VEV's), breaks the gauge group down to $SU(2)^6$ $SO(8)$, and leaves only one family of the multiplets massless. At special points of the moduli space, for example where $k$ of the family indices are aligned, the unbroken gauge group $SU(2)^k$ is enhanced to $Sp(2k)$.

We conclude with a number of remarks that in view of the analysis presented in this paper may be more general and could apply to a larger class of Type I blown-up orientifolds. In particular, a preliminary investigation of other orientifold models with non-Abelian singlets, indicates that the vacuum restabilization procedure still necessarily involves non-Abelian fields [21]. A large set of $Z_3$ $Z_3$ orientifolds (e.g., [3]) have only the fundamental and antisymmetric tensor representations of the gauge group in the light particle spectrum (i.e., those of the $-$ and $-$-type, respectively). It is conceivable that in general the type fields play an instrumental role in the vacuum restabilization of this class of blown-up orientifolds.

Our analysis demonstrates that the particular blown-up orientifold addressed in this paper is unlikely to have interesting phenomenological implications, since neither the surviving gauge group, generically $SU(2)^6$ $SO(8)$, nor the particle content, with generically only one family remaining light, are phenom enologically viable. Nevertheless, the approach sets the stage for further systematic analysis of other blown-up orientifolds, which may uncover potentially phenomenologically interesting Type I string vacua.

Uranga for correspondence and discussions. We would also like to thank M. Plummer for helpful discussions.
Appendix A: Enhanced Symmetries.

As an example, take two fields from the same family, and assume the components $^3_{[1\beta]}$ and $^3_{[3\beta]}$ have nonzero and equal VEVs. Label the SU(12) generators by $T^a_b$, where

$$T^a_b (\psi) = \frac{a}{c} b \psi] + \frac{a}{d} b \psi]$$

Then, the unbroken generators in the SU(4) subgroup are $(T^1_1;T^1_2;T^1_3$ and $(T^4_3;T^4_4), which correspond to SU(2)^2$; as well as $T^1_3; T^1_2; T^3_1; T^3_2 + T^3_3; T^3_4; T^3_1 + T^3_2$. It is straightforward to show that the remaining gauge group is Sp(4). Generalizing to the case with $k$ factors of fields aligned in the family indices, 3k generators remain unbroken from the obvious SU(2)^k subgroup. In addition, there are 4 unbroken generators for each pair of fields. Therefore, the total number of unbroken generators is $3k + 4k(k-1)/2 = k(2k+1)$, and the unbroken gauge group can be shown to be Sp(2k). There are six broken diagonal generators, which are the SU(12) generators not in SU(2)^6 and that of the anomalous U(1). The off-diagonal generators which connect factors from different families are also broken, as are the linear combinations of the off-diagonal generators that are orthogonal to the generators in the extensions of SU(2)^k to Sp(2k).

Appendix B: Directions Involving Non-Overlapping Polynomials.

We will simply illustrate with two examples involving an SU(4) subgroup of SU(12) and two fields.

As we have seen in Appendix A, the single monomial $^1_{[1\beta]}^1_{[3\beta]}$ breaks SU(4) to Sp(4), while $^1_{[1\beta]}^2_{[3\beta]}$ leaves SU(2)^2 unbroken. As an example of a non-overlapping polynomial in a different direction, consider $^1_{[1\beta]}^1_{[3\beta]}$ (where the first (second) pair of fields have VEVs $v_1$ ($v_2$)). Although this breaks each individual SU(4) generator, there are six unbroken linear combinations. These are $t_1; T^1_2; T^3_4; t_2; T^1_4; T^3_1 + T^3_2$, and their Hermitian conjugates, as well as the Hermitian generators $h_1; T^1_1; T^3_2 + T^3_3; T^3_4; h_2; i(T^1_2 + T^1_3; T^3_1; T^3_2).$ Here and $h_2$ commute with each other and the $t_i$. The six surviving generators correspond to an unbroken SU(2)^2, with the canonical SU(2) generators given by the combination of the $t_i$ and the $h_i$. This class of directions involves 5 real modulus. There are 8 massless complex fields associated with the SU(4) subgroup. Two families of states become massive and one remains massless.

An extension of this example utilizes all three families, i.e., $^1_{[1\beta]}^1_{[3\beta]}$ (where the first (second) pair of fields have VEVs $v_i; i = 1; 2; 3$ for the three pairs. In this case, there are three Hermitian generators, $h_2 ; i(t_1; T^1_2)$, and $i(t_2; T^1_3)$, of a surviving SU(2). There are 7 real moduli for these examples, and 5 massless complex fields. All three families of states become massive.
