We study the properties of M and F theory compactifications to three and four dimensions with background fluxes. We provide a simple construction of supersymmetric vacua, including some with orientifold descriptions. These vacua, which have warp factors, typically have fewer moduli than conventional Calabi-Yau compactifications. The mechanism for anomaly cancellation in the orientifold models involves background RR and NS fluxes. We consider in detail an orientifold of $K3 \times T^2$ with background fluxes. After a combination of T and S-dualities, this type IIB orientifold is mapped to a compactification of the SO (32) heterotic string on a non-Kähler space with torsion.
1. Introduction

The realization that certain string compactifications can be described in multiple ways has provided a significant improvement in our understanding of non-perturbative string dynamics. Among the more interesting compactifications are those with \( N = 1 \) and \( N = 2 \) supersymmetry in four dimensions. An intriguing class of such four-dimensional vacua are described by compactifying \( F \) theory on a Calabi-Yau four-fold \( M \). These vacua are naturally related to compactifications of type IIA string theory and \( M \) theory to two and three dimensions, respectively. The strong coupling limit of type IIA compacted on \( M \) is well described by the three-dimensional theory obtained by compactifying \( M \) theory on the same four-fold. If the four-fold admits an elliptic fibration with base \( B \), then we can consider a particular degeneration of this \( M \) theory compactification in which the area of the elliptic fiber shrinks to zero. In this limit, \( M \) theory on the four-fold goes over to type IIB compacted on the base \( B \) with a varying coupling constant. The coupling constant is of the elliptic fiber. This four-dimensional type IIB vacuum is known as an \( F \) theory compactification.

Among the novel features of these vacua is the need to cancel a tadpole anomaly. For this class of compactifications, the anomaly is given by \( \chi = 24 \), where \( \chi \) is the Euler characteristic of the four-fold. If \( \chi = 24 \) is integral, then the anomaly can be cancelled by placing a sufficient number of spacetime filling branes on points of the compactification manifold \([1]\). For type IIA, the required branes are strings, while in \( M \) and \( F \) theory, \( m \)embranes and \( D \)3-branes are required, respectively.

However, there is at least one other way of cancelling the anomaly in type IIA or \( M \) theory, which is by introducing a background \( \mu \)-\( x \) for the four-form field strength \( \mu \) \([3]\). The \( \mu \)-\( x \) contributes to the membrane tadpole in \( M \) theory through the Chern-Simons interaction,

\[
Z \quad C \wedge G \wedge G : \quad (1.1)
\]

For cases where \( \chi = 24 \) is not integral, \( \mu \)-\( x \) is actually required to obtain a consistent vacuum. In general, the anomaly can be cancelled by a combination of background \( \mu \)-\( x \) and branes. With \( n \) background branes, the tadpole cancellation condition

\[
\frac{1}{24} = \frac{1}{8} \quad Z \quad C \wedge G + n; \quad (1.2)
\]

must be satisfied for type IIA or \( M \) theory \([4]\).
Compactifications with $G$-ux have a number of interesting features, but have received little attention. The goal of this paper is to explore some of the properties of these vacua. In the following section, we review the results of [3] where conditions on supersymmetric vacua with $G$-ux were derived from eleven-dimensional supergravity. These conditions are quite difficult to satisfy. As a consequence, the presence of $G$-ux typically freezes some of the geometric moduli of the four-fold in a way that we describe.

Some of these M-theory vacua can be lifted to four-dimensional $N=1$ F theory vacua. The corresponding F theory vacua have background $G$-uxes of two kinds. The first kind involves non-zero NS and RR three-form field strengths, denoted $H$ and $H^0$, respectively. The three-form $G$-uxes contribute to the D 3-brane tadpole through the type IIB supergravity interaction,

$$Z \, \, D^+ \wedge H \wedge H^0$$  \hspace{1cm} (1.3)$$

where $D^+$ is the four-form gauge field. In the second kind of background, some of the seven-brane gauge fields have non-zero instanton number. In F theory, this possibility has been discussed in [4]. These instantons contribute to the D 3-brane tadpole through the seven-brane world-volume coupling,

$$Z \, \, D^+ \wedge F \wedge F$$  \hspace{1cm} (1.4)$$

where $F$ is the field strength for the seven-brane gauge field.

F theory is a useful description of these compactifications only when the base $B$ is large compared to the string scale. However, for special choices of four-fold M, F theory can be related to a type IIB orientifold which is a complete perturbative string theory [5]. In turn, some of these IIB orientifolds can be related to type I compactifications via T-duality. Largely for their simplicity, orientifolds of tori are most commonly studied. In conventional models, tadpole cancellation is achieved by adding branes: either D 9 and D 5-branes or D 7 and D 3-branes depending on the choice of orientifold action. In four dimensions, the possibility of using the type IIB interactions (1.3) and (1.4) to cancel the D 3-brane tadpole suggests that novel orientifolds should exist with backgrounds involving $H$ and $H^0$-uxes and gauge-field instantons. The possible types of orientifold are then classified by the choice of $C$-ux and $G$-ux in M theory on $M$.

In section three, we present examples of vacua with $G$-ux, including a simple orbifold construction and an example where $G$-ux is required. In the final section, we consider an example of a type IIB orientifold with constant background $H$ and $H^0$-uxes. Depending on
the choice of background $\mathrm{ux}$, the model has either $N=1$ or $N=2$ spacetime supersymmetry.

The compactification space $B$ is conformal to $K3 \times T^2$. This orientifold is related to $F$ theory on $K3 \times K3$, some aspects of which have been discussed in [7].

However, our interest is largely with a heterotic dual of this orientifold. By $T$-dualizing along the $T^2$, we map the IIB orientifold to a type I compactification on a new space $B^0$ with non-zero $H^0$-torsion. A further S-duality turns the type I vacuum into a perturbative $SO(32)$ heterotic vacuum with non-zero H-ux. The non-Kahler space $B^0$ is no longer conformally Calabi-Yau. This is a concrete example, possibly the first, of a four-dimensional string compactification with torsion.

There are a number of promising directions to explore. For example, associated to each of the type I/heterotic supergravity solutions is a world-sheet conformal $\mathcal{E}$d theory. Finding ways of constructing and analyzing these conformal $\mathcal{E}$d theories is a potentially rewarding enterprise. There should be analogues in this more general class of compactifications of phenomena associated with Calabi-Yau compactifications, such as mirror symmetry and its $(0;2)$ cousin [8, 9]. There are also intriguing connections between these solutions and the work of [10, 11, 12]. During the completion of this project, an interesting paper appeared [13] with some overlap with section 2.

2. Supersymmetry and G-ux

2.1. C- ed instantons

We begin by recalling the results of [3] for M theory compactified on an eight-dimensional Calabi-Yau manifold $M$. Let $M_{pl}$ denote the eleven-dimensional Planck scale. At leading order in a momentum expansion, the M theory effective action is given by eleven-dimensional supergravity. A product metric on $R^3 \times M$ is a solution to the supergravity equations of motion when the metric for the internal space $M$ is Ricci-flat. Let us parameterize $R^3$ by coordinates $x^\alpha$ where $\alpha = 0;1;2$ and the internal space $M$ by complex coordinates $y^a$ where $a = 1;\ldots;4$.

At next order in the derivative expansion, there are terms with eight derivatives which are therefore suppressed by six additional powers of $M_{pl}$. Among these terms is an interaction of the form $\{X_1|X_3, X_4\}$,

$$C^X_8(R);$$  \hspace{1cm} (2.1)
where $X_8$ is an eight-form constructed from curvature tensors. This term induces a tadpole for the $C$ - field. A way to cancel the tadpole is to turn on a non-trivial $G$ - ux. The metric is then modified from a simple product and takes the form:

$$ds^2 = e^{(y)} dx^a dx^b + e^{i} g^{ab} dy^a dy^b: \quad (2.2)$$

The metric $g$ for $M$ is Kähler and Ricci flat. Let us call the warped internal space $M^F$. The space $M^F$ is therefore conformal to a Calabi-Yau manifold.

There is also a non-vanishing four-form field strength $G$ on $M$ which satisfies the conditions:

$$G_{abcd} = G_{abcd} = 0; \quad g^{cd} G_{abcd} = 0: \quad (2.3)$$

The only other non-vanishing component of $G$ is given in terms of the warp factor,

$$G_{a} = \theta_a e^{\frac{x}{r}}: \quad (2.4)$$

Lastly, the warp factor satisfies the equation:

$$\left( e^{\frac{x}{r}} \right) = 4 X_8 \frac{1}{2} G \wedge G \left( 2 X^i \right)^8 (y_i): \quad (2.5)$$

The Laplacian and the Hodge star operator in (2.5) are defined with respect to $g$. We have included the possibility of membranes located at the points $y_i$ on $M^F$. The combination of $G$ - ux and membranes must satisfy (1.2).

The first condition in (2.3) tells us that $G$ is a $(2;2)$ form on $M$. Dirac quantization requires that the cohomology class $[G = ]$ be an element of $H^{(2;2)}(M; \mathbb{Z})$. If $= 24 \mathbb{Z}$ then $[G = 2 ]$ is an integer cohomology class $[4]$. The second condition in (2.3) is the analogue of the following condition for a two-form field strength $F$:

$$g^{ab} F_{ab} = 0: \quad (2.6)$$

In the two-form case, (2.6) implies that $F$ is anti-self-dual because,

$$\left( F \right)_{bc} =_{abcd} F^{cd} = (g_{ab} g_{cd} g_{ad} g_{eb}) F^{cd} = F_{ab}: \quad (2.7)$$

In the four-form case, we can again express the epsilon tensor in the following way:

$$abcdpqr = g_{ap} g_{bq} g_{cr} g_{ds} \quad \text{permutations:}$$
In much the same way as the two-form case (2.7), the conditions (2.3) imply that,

\[ G = G; \]  

(2.8)

where the Hodge star acts on the internal eight manifold with metric \( g \). This M theory background therefore involves an abelian ‘instanton’ of the C - eld. Lastly, let us rephrase the second condition (2.3) in terms of the Kahler form of \( M \),

\[ J \ i \gamma_{ab} d \alpha^a \wedge d \alpha^b; \]  

(2.9)

In terms of \( J \), the second condition states that the self-dual G - eld is primitive:

\[ J \wedge G = 0; \]  

(2.10)

This condition actually means that \( G \) is a singlet of the \( sl_2 \)-algebra generated by \( J \), its adjoint \( J^\dagger \) and their commutator \([J; J^\dagger]\). See, for example, [17].

2.2. Compactifications with extended supersymmetry

For compactifications on \( \mathbb{R}^3 \times M \), we decompose a 32 component Majorana-Weyl spinor under \( SO(2;1) \times SO(8) \) in the following way,

\[ 32 = (2;8_s) (2;8_c); \]  

(2.11)

For spaces \( M \) with holonomy \( SU(4) \) and not a proper subgroup, we can further decompose the \( SO(8) \) representations under \( SU(4) \):

\[ 8_s = 6 \ 1 \ 1; \]  

\[ 8_c = 4 \ 4; \]  

(2.12)

The two singlets in \( 8_s \) give the four real unbroken supersymmetries needed for a model with \( N = 2 \) supersymmetry.

If the holonomy of \( M \) is a proper subgroup of \( SU(4) \), the theory may have extended supersymmetry. See [18] for a discussion of the possible holonomies of an eight manifold. We will discuss two examples which appear in later discussion. The first is compactification on a hyperKahler manifold with holonomy \( Sp(2) \). On decomposing the \( 8_s \) and \( 8_c \) representations, we find

\[ 8_s = 5 \ 1 \ 1 \ 1; \]  

\[ 8_c = 4 \ 4; \]  

(2.13)
Therefore, this compactification can have $N = 3$ supersymmetry. Since the space is hyper-Kähler, there is a $\mathbb{P}^1$ of choices of complex structure. To see this, note that we can construct a complex structure tensor $J_{ij}$ from any complex covariantly constant spinor in the usual way:

$$J_{ij} = i y^{i} \gamma_{ij}.$$  

(2.14)

The indices $i; j = 1; \ldots; 8$ and $i$ are gamma matrices for $M$. For each of the $\mathbb{P}^1$ of choices for $\omega$, where $\omega$ has norm one, there is a corresponding complex structure tensor. The second example has holonomy $\text{Sp}(1) \times \text{Sp}(1)$. In this case,

$$8_s = (2; 2) \ (1; 1) \ (1; 1) \ (1; 1) \ (1; 1);$$

$$8_c = (2; 1) \ (2; 1) \ (1; 2) \ (1; 2);$$  

(2.15)

This compactification has at most $N = 4$ supersymmetry. There is a $\mathbb{P}^1 \times \mathbb{P}^1$ of complex structures. Whether there is extended supersymmetry actually depends on the choice of $G - \omega x$. To preserve more than $N = 2$ supersymmetry, the $G - \omega x$ must be a primitive $(2; 2)$ class with respect to more than a single complex structure. In section three, we will meet examples of $G - \omega x$ which do not preserve all the supersymmetry of the compactification manifold.

2.3. Kaluza-Klein reduction with a warp factor

In the presence of background $\omega x$es and a warp factor, the counting of light degrees of freedom is typically quite difficult because the equations obeyed by the metric and $C$-field fluctuations are coupled. The metric takes the form,

$$e_0 \frac{1}{g};$$  

(2.16)

where $g = e^g$. Let us begin by considering purely metric deformations. Since the metric $g$ is Calabi-Yau, in nilsine deformations of $g$ are classified in the usual way by elements of $H^{3,1}_{(\omega x)}$ and $H^{1,1}_{(\omega x)}$. However, those complex structure deformations that do not keep $G$ a $(2; 2)$ class become massive. Likewise, deformations of the Kahler structure that do not keep $G$ primitive become massive. In this way, we generically lose a large number of geometric moduli.

Let us take the generic case where $N = 2$ spacetime supersymmetry is preserved. The moduli that we wish to count appear in two kinds of multiplet: the first is the dimensional
reduction of a four-dimensional $N = 1$ chiral multiplet. The second is the reduction of an $N = 1$ vector multiplet. In three dimensions, the vector multiplet can be dualized to a chiral multiplet containing a dual scalar. Each surviving deformation in $H^3 \mu (M)$ gives rise to a chiral multiplet, while each deformation in $H^1 \mu (M)$ gives rise to the scalar field of a vector multiplet. The vector field itself comes from a C - field zero-mode.

Let us consider the effect of just a warp factor on the C - field equations. Without $G - \mu$, the C - field obeys the free - field equation,

$$d^* dC = 0; \quad (2.17)$$

By using the gauge invariance $C ! C + d\phi$, we can demand that C satisfy

$$d^* C = 0; \quad (2.18)$$

Combined with the field equation, this gives the usual condition,

$$b_C = 0; \quad (2.19)$$

Decomposing (2.19) into spacetime and internal components gives,

$$G \mu + e^{b_g} \frac{3}{2} e^{b_{ab}(a) a} C = 0; \quad (2.20)$$

The last two terms in (2.20) will look like mass terms from the perspective of the three-dimensional observer. The second term is conventional and leads to the usual hemonicity condition on the internal components of $C$. However, the third term is a new consequence of the warp factor.

In the presence of non-trivial background $G - \mu$, equation (2.17) for a fluctuation $\partial \partial C$ becomes:

$$d^* d\partial C = G^\mu d\partial C; \quad (2.21)$$

We have set all metric fluctuations to zero in (2.21). We decompose $C$ into a product of spacetime and internal fields,

$$C = (x)C^{(3)}(y) + A(x)C^{(2)}(y); \quad (2.22)$$

where we only consider spacetime multiplets with vector or scalar fields, and $C^{(n)}$ is an n-form on the eight manifold. We can dispense immediately with the counting of vector fields $A(x)$ since each zero-mode of $C^{(2)}$ pairs with a Kahler class deformation to give a vector multiplet. We only need to count the number of massless modes from $H^2 \mu (M)$ to count the number of vector multiplets.

The moduli source of moduli are the analogues of Wilson lines for the C - field. In the absence of $G - \mu$, any element of $H^2 \mu (M)$ gives rise to a zero-mode for $C^{(3)}$ and therefore a chiral multiplet. In the presence of $G - \mu$, the conditions on $C^{(3)}$ are modified. We can

---

1 Note that $H^3 \mu (M)$ is empty for a simply connected Calabi-Yau.
expand the left hand side of (2.21) as follows,

\[ d \wedge d \ C = d \ w^3 + d \ w d \ C^3 + d \ w (e^3 = \ w d C^3) ; \]  

(2.23)

where each Hodge star appearing on the right hand side is with respect to the unwarped spacetime and internal metrics.

Combining (2.23) with the right hand side of (2.21) gives the following set of equations:

\[ G \wedge d C^3 = 0; \]
\[ d \wedge G \wedge C^3 = 0; \]
\[ d \wedge d C^3 = 0; \]
\[ d \wedge d C^3 = e^3 \ w d C^3 = e^3 \ w d C^3 \wedge d C^3 g . \]

To satisfy the third equation in (2.24), we can set the gauge by demanding that,

\[ d C = 0; \]  

(2.25)

This choice differs from the usual gauge fixing condition (2.18) by an exact form. As a consequence of (2.25), \( d C^3 = 0 \). The first equation in (2.24) is a consequence of equation two which requires that,

\[ G \wedge C^3 = 0; \]  

(2.26)

This condition is the analogue of the primitivity condition (2.10) for the metric.

The right hand side of the final equation in (2.24) must vanish since this term gives a mass to the spacetime field. Requiring that the perturbation \( d C^3 \) take us to a supersymmetric vacuum implies that \( d C^3 \) must be self-dual, which in turn implies that \( C^3 \) is harmonic. Therefore any element of \( H^2 (M) \) which satisfies (2.26) gives rise to a chiral multiplet.

2.4. Lifting \( G \)-aux to \( F \) theory

If the eight manifold \( M \) is elliptically-bered with base \( B \), then by shrinking the volume of the fiber, we can lift our \( M \) theory compactification to a four-dimensional type IIB compactification on \( R^4 \times B \). Since the power of the warp factor is di erent for the spacetime and internal metric in (2.16), we might worry that the resulting four-dimensional metric breaks Lorentz invariance.
Let us first show that this is not the case. M theory on $T^2$ with area $A$ maps to type IIB on a circle $S^1$ with radius proportional to $1=A$. Locally, the warp factor rescales the metric sending:

$$A \mapsto e^{2A}:$$

However, this corresponds to rescaling the IIB circle metric by

$$\frac{1}{A^2} \mapsto e^{\frac{1}{A^2}};$$

which is precisely the power needed to obtain a Lorentz invariant four-dimensional metric.

How does the $G-$ UX lift to type IIB? Let us start with the $G_a$ component. This component has the form $dC^a$, and the this $C-$ UX lifts to a component of the four-form $D^a$ of type IIB:

$$C \mapsto D^a: \quad (2.27)$$

Note that $a$ is a spacetime index and that $dD^a$ is not required to be self-dual. What is required to be self-dual is the combination,

$$F^+ = dD^a - \frac{1}{2} B^0 \wedge H + \frac{1}{2} B \wedge H^0: \quad (2.28)$$

Therefore the presence of this spacetime $D^a$ does not imply that there is a $D^a$ in the internal space.

We can divide the remaining $G-$ UX involving $G_{abcd}$ into two cases. There could be a component of $G$ with no legs along the fiber. This component would map in the following way,

$$G_{abcd} \mapsto (dD)^+_{abcd}:$$

This UX breaks four-dimensional Lorentz invariance. By self-duality of $G$, this case also rules out the possibility of components with two legs along the fiber.

The remaining possibility is the case where $G$ is locally the product of a three-form on $B$ and a one-form in the fiber. In this case, we can also differentiate between two kinds of $G-$ UX. We can see this already in the relation between M theory on $K3=T^4=\mathbb{Z}_2$ and the type IIB orientifold of $T^2$ by $\mathbb{Z}_2$, where is world-sheet parity [19]. M theory on $T^4=\mathbb{Z}_2$ has 22 gauge- UXs obtained by reducing the $C-$ UX on the 22 forms in $H^2(K3;\mathbb{Z})$. The 22 forms on $T^4=\mathbb{Z}_2$ are grouped in the following way: there are 16 twisted sector $(1;1)$ forms. Each twisted sector form comes from an $A_1$ singularity so the gauge group is
enhanced to SU(2). The (2; 0) and (0; 2) forms descend from $T^4$ as do 4 more untwisted (1;1) forms. The gauge group is SU(2)$^4$ U(1)$^6$.

In the limit where $A!0$, the two untwisted sector forms corresponding to the class of the fiber and its Hodge dual are no longer normalizable. We can identify the remaining 20 forms with gauge-elds in the orientifold theory in the following manner: note that the action $(1)^{F_L}$ is an element of SL(2; Z) given by the matrix,

$$\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}; \quad (2:29)$$

which projects out both $B$ and $B^0$. The only components which survive the projection have a leg along $T^2$. The 4 Kaluz-Klein gauge-elds obtained by reducing $B$ and $B^0$ along one-cycles of $T^2$ are then identified with the 4 surviving untwisted sector forms of $T^4=\mathbb{Z}_2$. The 16 xed points coalesce into 4 groups of coincident $A_1$ singularities. The gauge group is enhanced from SU(2)$^4$! SO(8). The SO(8) arises in the orientifold picture from placing 4 D7-branes at the location of each O7-plane.

Therefore, if our $G$ -ux is localized around a singular fiber of the elliptic bration, it will lift to the eld strength of a seven-brane gauge-eld. The gauge-eld will have non-zero instanton number on the 4-cycle wrapped by the seven-brane. If there are multiple seven-branes then the gauge-group can be non-abelian as in the $T^4=\mathbb{Z}_2$ example. In this situation, the supergravity analysis is incomplete since the enhanced gauge symmetry is non-perturbative in M theory. From F theory, we certainly expect the gauge-eld to satisfy the non-abelian Donaldson-Uhlenbeck-Yau equation. Any holomorphic stable vector bundle would then give a supersymmetric solution.

For the most part, we will consider the last choice for $G$. In this case, we can express $G$ locally in terms of a basis for one-forms on the torus,

$$dz = dx + dy \quad dz = dx + dy;$$

in the following way,

$$\frac{G}{2} = dz^! \quad d\bar{z}^!; \quad (2:30)$$

where $2 H^{1,2}(B)$. The ux then lifts to a combination of the NS eld strength $H$ and RR eld strength $H^0$. The eld strengths are given in terms of $!$;

$$H = ! \quad !$$

$$H^0 = ! \quad !; \quad (2:31)$$

10
The anomaly cancellation condition then becomes,

\[ \frac{Z}{24} = n H \wedge H^0; \]  

(2.32)

where \( n \) is the number of D3-branes.

The NS 3-form strength \( H \) and the RR 3-form strength \( H^0 \) are naturally arranged in an \( SL(2;\mathbb{Z}) \) doublet of type IIB supergravity

\[
\begin{pmatrix}
H^0 \\
H
\end{pmatrix}
\]

(2.33)

In terms of \( ! \),

\[
\frac{p}{2} (!^a) \quad \frac{p}{2} (!^b)
\]

In a generic F theory compactification, the IIB fields undergo non-trivial monodromies by elements of \( SL(2;\mathbb{Z}) \) around singular fibers. Under an \( SL(2;\mathbb{Z}) \) transformation

\[
\begin{pmatrix}
1 & a \\
b & 1
\end{pmatrix}
\]

and transform in the following way,

\[
\begin{pmatrix}
c + d \\
c + d
\end{pmatrix}^{1=2}
\]

(2.34)

Our \( H \) and \( H^0 \) fields can therefore be rotated non-trivially by \( SL(2;\mathbb{Z}) \) as we move along the base space \( B \).

3. Constructing Vacua with G-Flux

3.1. K3 K3

The first example that we will consider is \( M \) theory on \( K3_1 \times K3_2 \). This compactification space gives \( N=4 \) supersymmetry in three dimensions. The anomaly =24 = 24 which must be cancelled by a combination of branes and G-ux. We therefore require that,

\[
\frac{1}{2} \quad \frac{G}{2} \wedge \frac{G}{2} \quad 24;
\]

Unfortunately, the natural complex combinations of \( H \) and \( H^0 \) are usually denoted \( G \) and \( G \) in the literature. To avoid confusion, we have chosen the notation \( G \) and \( G \). See [20] for an explanation of the mapping between the \( SU(1,1)=U(1) \) and the \( SL(2;\mathbb{R})=U(1) \) parametrizations of the supergravity moduli space.
Let $J_1$ and $J_2$ denote the Kähler forms for $K_3_1$ and $K_3_2$, respectively. We will initially choose $G_{-ux}$ of the form,

$$\frac{G}{2} = !_1 ^!_2;$$

(3.1)

where $!_i \in H^{1,2}(K_3;\mathbb{Z})$. Each $!_i$ must also be primitive with respect to $J_i$. By definition, each $!_i$ is an element of the Picard group $\text{Pic}(K_3_i)$.

For a generic $K_3$, the Picard group will be empty. To find a solution, let us construct a $K_3$ surface in the following way: take a hypersurface in $\mathbb{P}^1 \times \mathbb{P}^1 \times \mathbb{P}^1$ of degree $(2;2;2)$. There are three natural elements of $\text{Pic}(K_3)$ which we will denote $C_1;C_2;C_3$. These classes are determined by the three hyperplanes,

$$\begin{align*}
\text{fp}g &\quad \mathbb{P}^1 \times \mathbb{P}^1; \\
\mathbb{P}^1 &\quad \text{fp}g \times \mathbb{P}^1; \\
\mathbb{P}^1 &\quad \mathbb{P}^1 \times \text{fp}g;
\end{align*}$$

(3.2)

for $\text{fp}g$ a point. With a standard abuse of notation, we will use $C_i$ to denote both the cohomology class and the cycle dual to the Poincaré dual of $C_i$. The intersection matrix for the $C_i$ is easily computed. Any two distinct $C_i$ intersect on a $\mathbb{P}^1$. A quadratic in $\mathbb{P}^1$ gives two points. The self-intersection number of any $C_i$ vanishes, so we obtain the following intersection matrix:

$$\begin{bmatrix}
0 & 1 \\
0 & 2 & 2 \\
2 & 2 & 0
\end{bmatrix}.$$

(3.3)

We can take $J = C_1 + C_2 + C_3$ as the Kähler form for this surface. As our basic primitive class, let us take $J = C_1 + C_2$: The self-intersection number is $4$.

We can take both $K_3_1$ and $K_3_2$ to be surfaces of the kind described above. Each space is endowed with a primitive form denoted $1$ and $2$: To cancel the anomaly completely, we can place $16$ membranes on $K_3_1$ and $K_3_2$ and turn on,

$$\frac{G}{2} = 1 ^!_2;$$

(3.4)

We can also cancel the anomaly completely without branes in the following way: in addition to, let us consider the primitive class $J = C_1 + C_3$ with self-intersection $4$. Then $J = 2$ and we can turn on the $ux$,

$$\frac{G}{2} = (1 + 1)^!_2;$$

(3.5)
Note that this choice of $G-ux$ is a primitive $(2;2)$ class with respect to each of the $P^1 \times P^1$ choices of complex structure. The full $N=4$ supersymmetry is therefore preserved.

As a second more exotic example, let us consider the $K3$ surface obtained by quotienting a square $T^4$ with coordinates $(z^1; z^2)$ by,

$$g_1 : (z^1; z^2)! (iz^1; iz^2); \quad (3.6)$$

Under this $\mathbb{Z}_4$ quotient action, there are no untwisted $(1;1)$ forms. The resulting $K3$ has Picard number 20 [21]. Linear combinations of the twenty twisted sector $(1;1)$ forms are therefore integral classes. This implies that combinations of $(2;0)$ and $(0;2)$ forms are also integral classes because $H^2(K3; \mathbb{Z})$ has 22 elements. The intersection matrix for these transcendental integral classes is given by [21]

$$\begin{pmatrix}
2 & 0 \\
0 & 2
\end{pmatrix}.$$ 

For this orbifold case, we note that the untwisted sector holomorphic $(2;0)$ form

$$= dz^1 dz^2 \quad (3.7)$$

satisfies $\frac{R}{R} = 4$. Let us take both $K3_1$ and $K3_2$ to be $T^4 = \mathbb{Z}_4$ orbifolds. Then the $(2;2)$ form

$$f_1 \overline{1^2} + 1 \overline{2^2} g; \quad (3.8)$$

de ned on $K3_1$, $K3_2$ is primitive and integral.

We also require a class $G$, which we take to be a primitive $(1;1)$ class with self-intersection 4. For example, the class obtained by taking the difference of the cycles coming from the resolution of the

$$(z^1 = 1z^2 = 1z^2); \quad (z^1 = iz^2; z^2 = iz^2)$$

fixed points in the $(g_1)^2$ twisted sector. This class has zero intersection with every other $(1;1)$ form. There are a number of other choices for $G$. We can then cancel the anomaly completely with the following $G-ux$:

$$\frac{G}{2} = 1 \overline{1^2} + 1 \overline{2^2} + 1 \overline{2} \quad (3.9)$$

Note that this choice of $G-ux$ does not preserve the full $N=4$ supersymmetry. Varying the complex structure of $K3_i$ rotates $i$ and $J_i$ into each other. The resulting $G$ is no
longer supersymmetric. Therefore, only $N=2$ supersymmetry survives. We will construct another example of a K3 K3 compactification with $G-\text{ux}$ in the following section.

Before leaving this case, let us see how special choices of $G-\text{ux}$ appear in the $E_8 \times E_8$ heterotic dual. For illustration, let us take the form (3.1) for our $G-\text{ux}$. M theory on K31 K32 has a dual realization in terms of the heterotic string on T3 K32. Away from points of enhanced symmetry, the heterotic string on T3 has 22 abelian gauge-elds. As mentioned before, the gauge-elds arise in M theory by reducing the C-eld on the 22 elements of $H^2(K3;\mathbb{Z})$. We can then express $G$ reduced on K31 in terms of the eld strength $F$ for an abelian gauge-eld,

$$\frac{G}{2} = F^\wedge i_1;$$

We then take $F = !2$, which corresponds on the heterotic side to taking an abelian connection with some instanton number on K32. Any membranes used to cancel the anomaly correspond to heterotic ve-bridges wrapping T3. For the 16 gauge-elds coming from the Cartan of $E_8 \times E_8$, supersymmetry requires that,

$$g^{ab}F_{ab} = 0;$$

and that $F$ be a (1;1) form. Clearly these constraints are satisfied by any $G-\text{ux}$ of the form (3.1).

3.2. Some orbifold examples with constant $G-\text{ux}$

The next class of examples that we will construct have orbifold singularities. These examples all have constant $G-\text{uxes}$. In cases with $F$ theory lifts, the corresponding H and $H^6$-uxes will be also be constant. Let $(z^1; z^2; z^3; z^4)$ coordinatize $T^8$. Since we will consider only $\mathbb{Z}_2$ quotients, we restrict $T^8$ to $T^2 \times T^2 \times T^2$ with each $T^2$ rectangular. We choose each $T^2$ to have periods,

$$dz^i = i \frac{1}{i};$$

where $\frac{1}{i}$ and $\frac{1}{j}$ are the x and y one-cycles.

Since our spaces will be $\mathbb{Z}_2$ quotients of $T^8$, the metric is at away from the singularities and the Kahler form is,

$$J = \sum_i dz^i \wedge dz^i;$$

(3.10)
Let us take \( G \) to have the form,
\[
\frac{G}{2} = A dz^1 dz^2 dz^3 dz^4 + A dz^1 dz^2 dz^3 dz^4 + B dz^1 dz^2 dz^3 dz^4 + B dz^1 dz^2 dz^3 dz^4 + C dz^1 dz^2 dz^3 dz^4 + C dz^1 dz^2 dz^3 dz^4.
\]
(3.11)

This choice of \((2;2)\) form certainly satisfies \( J^G = 0 \). By construction, \( G \) is real. We also require that \( G=2 \) be (half)-integer quantized. Requiring that \( G=2 \) be integral over all four-cycles of \( T^8 \) gives the conditions:
\[
2 \text{Re} A \quad \text{Re} B \quad \text{Re} C \in 2 \mathbb{Z}; \quad 2 \text{Im} A \quad \text{Im} B \quad \text{Im} C \in 2 \mathbb{Z}:
\]
(3.12)

The anomaly condition becomes,
\[
16 \Re j + B \Re j + C \Re j + n = \frac{24}{24};
\]
(3.13)

where \( n \) is the number of branes.

Since we will consider orbifolds of \( T^8 \), we also need to ensure the following two conditions: the first is that \( G=2 \) satisfy the quantization condition (3.12) modified to take the orbifold action into account\(^3\). The second condition is that \( G=2 \) has (half)-integer intersections with all 4-cycles coming from the twisted sectors. We will need to check both these conditions on a case by case basis, but one possibility can be removed immediately. Certain twisted sectors can give rise to operators \( O \) which correspond to \((2;2)\) forms. However, the two-point function of \( O \) with \( G \) satisfies,
\[
< G O > = 0;
\]
(3.14)

because \( O \) is charged under the orbifold gauge group. The remaining possibility is three-point functions of the form,
\[
< G P P^0 > ;
\]
(3.15)

where the two-forms \( P \) and \( P^0 \) carry opposite discrete charge.

As a first example of this kind, let us revisit \( K3_1 \quad K3_2 \) where we realize \( K3_1 \) by \( T^4 = \mathbb{Z}_2 \). We therefore quotient \( T^8 \) by \( \mathbb{Z}_2 \quad \mathbb{Z}_2 \) generated by,
\[
g_1 : (z^1; z^2)! \quad (z^1; z^2) \\
g_2 : (z^3; z^4)! \quad (z^3; z^4);
\]

\(^3\) We wish to thank J. Polchinski for correcting our original quantization condition.
The form (3.11) is invariant under this action. The first issue is how the quantization condition is modified. The volume of the fundamental domain for the orbifold has volume reduced by \( l = 4 \). For example, we can parametrize the fundamental domain by restricting the range of \( x_1 \) and \( x_3 \) to be 0 to 1 rather than 0 to 1. There are now 4-cycles with \( l = 4 \) the volume. These give a modified quantization condition,

\[
\frac{1}{2} \text{Re} A \text{Re} B \text{Re} C g 2 \mathbb{Z}; \quad \frac{1}{2} \text{Im} A \text{Im} B \text{Im} C g 2 \mathbb{Z}; \quad (3.16)
\]

and anomaly constraint:

\[
4 A \bar{A} + B \bar{B} + C \bar{C} + n = \frac{24}{24}; \quad (3.17)
\]

For appropriate choices of \( A, B, \) and \( C \), we obtain supersymmetric compactifications. For example, the choice

\[
A = 2 \quad B = 1 \quad C = 1;
\]

cancels the anomaly without any branes. To check that \( G = 2 \) is an integer form, we also need to compute (3.15). First we note that \( G^4 \), \( G^3 \), \( G^2 \), \( G^1 \) for the volume form of \( K_3 \). This guarantees that if \( \mathcal{P} \) and \( \mathcal{P}' \) are two-forms from the same \( K_3 \), (3.15) vanishes. The remaining possibility is when \( \mathcal{P} \) and \( \mathcal{P}' \) are charged under different \( \mathbb{Z}_2 \) actions in which case (3.15) vanishes by charge conservation.

A more interesting example is the \( \mathbb{Z}_2 \) quotient by the action,

\[
g_1 : (z^1; z^2; z^3; z^4)! (z^1; z^2; z^3; z^4);
\]

This space has singularities which cannot be resolved. However, it is perfectly fine as an \( \mathcal{M} \) theory or type IIA compactification. String orbifold techniques give \( G = 24 = 16 \). The Hodge numbers are:

\[
H^{2,0} = 6; \quad H^{1,1} = 16; \quad H^{2,1} = 0; \quad H^{3,1} = 16; \quad H^{2,2} = 292;
\]

As usual, \( H^{4,0} = 1 \). There are now 4-cycles with volume reduced by \( l = 2 \). These give the following quantization condition:

\[
\frac{1}{2} \text{Re} A \text{Re} B \text{Re} C g 2 \mathbb{Z}; \quad \frac{1}{2} \text{Im} A \text{Im} B \text{Im} C g 2 \mathbb{Z}; \quad (3.18)
\]

and anomaly constraint:

\[
8 A \bar{A} + B \bar{B} + C \bar{C} + n = \frac{24}{24}; \quad (3.19)
\]
Tuning $A;B$ and $C$ appropriately gives solutions that cancel the tadpole either partially or completely. For example, the choices $A = 1 + i$ or $A = B = 1$ both completely cancel the tadpole with just $G - u x$. Checking that $G=2$ is integer is easy in this case because there are no twisted sector two-forms $P$. The only operators are four-forms $sO$ whose intersection with $G=2$ vanishes.

Our next example is the symmetric product of $K3$. It is of a quite different flavor because we will not be able to find a supersymmetric solution with $u x$ of the form (3.11). We define the quotient by the action,

$$g_1 : (z^1; z^2)! (z^1; z^2)$$

$$g_2 : (z^3; z^4)! (z^3; z^4)$$

$$g_3 : (z^1; z^2; z^3; z^4)! (z^3; z^4; z^1; z^2):$$

This compactification space has $N = 3$ supersymmetry in three dimensions because $S^2(K3)$ is a hyper-Kähler space. In this case, $G = 24 = 27 = 2$. The Hodge numbers are:

$$H^{2,0} = 1; \quad H^{1,1} = 21; \quad H^{2,1} = 0; \quad H^{3,1} = 21; \quad H^{2,2} = 232.$$}

To obtain a consistent compactification, we therefore need to turn on $G - u x$. Note that invariance under the $g_3$ action requires that $B$ and $C$ be real. In this case, $G=2$ can be half-integer quantized [16]. At first sight it seems that this additional freedom is not enough to find a solution to (3.13). Let us begin by examining the integrality condition on $G=2$. For the moment, let us ignore the effect of quotienting by $g_3$ and start by considering just $K3$. The integrality condition becomes,

$$\text{Re} A \quad B \quad C \quad 2 \quad \mathbb{Z}; \quad \text{Im} A \quad g \quad 2 \quad \mathbb{Z}.$$ \hspace{1cm} (3.20)

Including the effect of symmetrizing can only make this condition more stringent. The anomaly constraint (including the effect of symmetrizing) becomes,

$$2 \; \text{Re} J + B^2 + C^2 + n = \frac{27}{2}:$$ \hspace{1cm} (3.21)

Let us derive the condition that the intersection of $G=2$ with all twisted sector states is half-integral. The intersections with the twisted sector states corresponding to the generators $g_1$ and $g_2$ vanish by exactly the arguments given for the $T^8 = (\mathbb{Z}_2)^2$ example above. We therefore only need to check the condition for twisted sector states generated by
$g_3$. For this purpose, it is easier to consider $S^2(T^4)$ rather than $S^2(K3)$. This simplification is possible because the unique twisted sector $(1;1)$ form on $S^2(K3)$ descends from the unique twisted sector $(1;1)$ form on $S^2(T^4)$.

Denote $S^2(T^4)$ by $X$ and let $\mathcal{F}$ be its resolution obtained by blowing up over the exceptional locus which is the diagonal four-torus $T^4_D$. Let $Y = T^4 - T^4$ and $\mathcal{F}$ be the space obtained by blowing up $Y$ over the diagonal $T^4_D$. There are projections $q$ and $p$ from $\mathcal{F}$ to $Y$ and $\mathcal{F}$ to $X$ respectively. The involution $i: Y \rightarrow X$ lifts to an involution $s: \mathcal{F} \rightarrow \mathcal{F}$, which is branched over the exceptional divisor. We can summarize this information in the following commutative diagram:

$$
\begin{array}{ccc}
\mathcal{F} & \xrightarrow{s} & \mathcal{F} \\
\# q & \downarrow & \# p \\
Y & \xrightarrow{i} & X
\end{array}
$$

(3.22)

Now consider a form $v$ on $H^4(Y; \mathbb{Z})$. For example, the form defined in (3.11). This form can be pulled back to $\mathcal{F}$ giving $q! 2H^{2,2}(\mathcal{F})$ and then pushed forward to a form:

$$
\hat{v} = s(q!) 2H^{2,2}(\mathcal{F})
$$

Note that $\mathcal{F}$ is a double cover of $\mathcal{F}$. Therefore $s(v) = 2v$ for any form $v$ on $\mathcal{F}$ and we have $s \hat{v} = 2q!$. Consider the integral twisted sector $(1;1)$ form $e 2H^{1,1}(\mathcal{F}) \setminus H^4(\mathcal{F}; \mathbb{Z})$ which is Poincaré dual to the exceptional divisor in $\mathcal{F}$. Then

$$
s \hat{e} = 2t;
$$

where $t 2H^{1,1}(\mathcal{F}) \setminus H^4(\mathcal{F}; \mathbb{Z})$ is Poincaré dual to the exceptional divisor in $\mathcal{F}$. This is true again because $\mathcal{F}$ is a double cover of $\mathcal{F}$ and $s$ is branched over the exceptional divisor. The relevant three point function we wish to compute is

$$
<\hat{e}^2, \hat{e}, e>_{\mathcal{F}} = \frac{1}{2} <s(e^2, e)>_{\mathcal{F}} = 2 <t^2, se, e>_{\mathcal{F}} = 4 <t^2, q!, e>_{\mathcal{F}}.
$$

Since the normal bundle of the diagonal $T^4_D$ is trivial, we see that the exceptional divisor $D$ corresponding to $t$ is just $D^1 = T^4_D$. The intersection is then

$$
8 <T^4_d, q!, e>_{\mathcal{F}} = 8 <T^4_d, ! >_{\mathcal{F}}.
$$

\footnote{We wish to thank D.-E. Diaconescu for explaining the following argument.}
But this can now be readily computed: first it is easy to check that the contributions from the $A$ and $A'$ terms vanish because the forms then vanish on $T_0^4$. The other terms yield the following integrality condition for half-integral $G = \mu x$,

$$128 (B + C) 2 \mathbb{Z}:$$

While this was derived for $S^2(T^4)$, the same condition can be seen to hold for the symmetric product of $K3$ in the orbifold limit.

What remains is for us to find a solution to these integrality conditions, and here we meet a problem. Even the weaker condition (3.20) requires that one of $ReA, B$, or $C$ be integral. For example, we can choose

$$A = a + ie; \quad B = b=2; \quad C = c=2;$$

where $a, e, b, c$ are integers, and where $b, c$ are both even or both odd. However, the anomaly cancellation condition imposes the constraint:

$$a^2 + e^2 + \frac{b^2 + c^2}{4} + \frac{n}{2} = 6 + \frac{3}{4}:$$

This condition cannot be satisfied! There is therefore no choice of $\mu x$ of the form (3.11) which preserves supersymmetry in this example.

Lastly, we consider an example which gives $N=2$ supersymmetry in three dimensions. We quotient by,

$$g_1 : (z^1; z^2)! (z^1; z^2)$$
$$g_2 : (z^1; z^3)! (z^1; z^3)$$
$$g_3 : (z^2; z^4)! (z^2; z^4):$$

$^5$ The symmetric product is a highly singular space. However, we can smooth the space by blowing up the symmetric product $X = S^2(K3)$ over the fixed locus. This amounts to replacing $X$ by the Hilbert scheme of points $K3^{[2]}$. See, for example, [22]. In a diagram analogous to (3.22), $\mathfrak{X} = K3^{[2]}$ and $p : K3^{[2]}! X$. If we want $p(G = 0)$ to be a primitive element of $H^2(K3^{[2]}; \mathbb{Z})$, we need to impose at least one additional condition on (3.11). The Kähler class of $K3^{[2]}$ has a term proportional to the class of the exceptional divisor. To ensure primitivity, we can require that $G = 0$ vanish on the fixed locus, which implies that $B = C$. This is a natural way to get a smooth hyperkähler compactification. We wish to thank L.Gottsch for pointing out this generalization.
The quotient group essentially inverts all possible pairs of tori. For this case, $=24 = 28$. The Hodge numbers are:

$$H^{2,0} = 0; \quad H^{1,1} = 100; \quad H^{2,1} = 0; \quad H^{3,1} = 4; \quad H^{2,2} = 460.$$  

The integrality condition becomes,

$$\begin{align*}
\frac{1}{4} \text{Re} A & \quad \text{Re} B \quad \text{Re} C \in \mathbb{Z}; & \frac{1}{4} \text{Im} A & \quad \text{Im} B \quad \text{Im} C \in \mathbb{Z}; \quad (3.23)
\end{align*}$$

with anomaly constraint,

$$2 \not{A} \not{f} + B \not{f} + C \not{f} + n = 28; \quad (3.24)$$

As a sample choice of $G - \text{ux}$, we can take

$$A = 2; \quad B = 2; \quad C = 0;$$

which cancels the anomaly completely with $n = 12$ branes. To check that $G = 2$ is integer, we need to check that it has integer periods over all integer homology cycles. For the untwisted sector cycles, this reduces to verifying (3.23), which is obvious. For the twisted sector cycles, it is easy to repeat the arguments presented for the previous $T^6 = (\mathbb{Z}_2)^2$ example to show that all three point functions of type (3.15) vanish.

### 3.3. An orientifold example

In a similar way, we can construct four-dimensional orientifold examples with constant uxes. We start with an orbifold of the form $T^6 = \cdot$. Again for simplicity let us take $T^6 = T^2 \cdot T^2 \cdot T^2$ with each factor rectangular and coordinates $(z^1, z^2, z^3)$. We can view an orientifold of $T^6$ as a special point in the moduli space of F theory compacted on the elliptically-bered four-fold [3],

$$M = \frac{T^6}{\mathbb{Z}_2};$$

where the $\mathbb{Z}_2$ action inverts both $z^3$ and the coordinate, $z^4$, of the ber $T^2$. This F theory compactation reduces to the orientifold of type IIB on $T^6$ by the action $(1)^F \mathbb{Z}_2$ where the $\mathbb{Z}_2$ inverts $z^3$. This action produces various O7-planes at complex codimension one fixed sets on $T^6$. By adding D7-planes, we can cancel the O7-plane charge. Fixed
points under group elements in the product of \((1)^F\mathbb{Z}_2\) and generate O 3-planes. The total D 3-brane tadpole is \((M) = 24\).

As a specific example, we can take the following generators for 
\[ g_1 : (z^1, z^2) \] \[ g_2 : (z^1, z^3) \]

The resulting Calabi-Yau \(T^6\) has Hodge numbers \(h^{1,1} = 51; h^{2,1} = 3\). The associated four-fold \(M\) is the example of section 3.2. This orientifold and its relation to F theory has been studied in [23-24]. To cancel the anomaly with 12 D 3-branes, we can turn on the uxex

\[
\begin{align*}
H &= A \, dz^1 dz^2 dz^3 + A \, dz^1 dz^2 dz^3 + B \, d\bar{z}^1 d\bar{z}^2 d\bar{z}^3 + B \, d\bar{z}^1 d\bar{z}^2 d\bar{z}^3; \\
H^0 &= A \, idz^1 dz^2 dz^3 + A \, idz^1 dz^2 dz^3 + B \, id\bar{z}^1 d\bar{z}^2 d\bar{z}^3 + B \, id\bar{z}^1 d\bar{z}^2 d\bar{z}^3; \\
\end{align*}
\]

(3.25)

with the choice:

\[ A = 2; \quad B = 2. \]

It is interesting to note that the same four-fold can give rise to many different orientifolds depending on the choice of \(C\) and \(G = \text{ux}x\). This point will be explored more fully elsewhere.

4. A Heterotic Compactification With Torsion

In this section, we will construct an example of a four-dimensional SO(32) heterotic string compactification with torsion. This particular example has either \(N = 1\) or \(N = 2\) supersymmetry, depending on the choice of \(\text{ux}x\). We begin with type IIB compacted on an orientifold of \(K3 \times T^2\). After a series of T and S dualities, we will arrive at our heterotic model.

The initial IIB supergravity metric is conformal to the metric on \(K3 \times T^2\). The solution still possesses two isometries along the \(T^2\). Two T-dualities along the two circles of \(T^2\) send \((1)^F\mathbb{Z}_2\) to \([10]\). In other words, it takes our F theory compacted with \(\text{ux}x\) to a type I theory. In the subsequent discussion, we will specify the resulting type I background. If we choose to use only D 3-branes and no background uxex to cancel the anomaly, the resulting theory is type I on \(K3 \times T^2\) with 24 D 5-branes wrapping the \(T^2\). With background \(\text{ux}x\)s, the result is quite different. We will find type I compacted on a space \(B^0\) with the following properties:
1. It is a complex manifold which is not Kahler, or even conformally Calabi-Yau.
2. It has vanishing first Chern class.
3. It has a non-zero $H^0$-ux.

After a further S-duality, we end up with the SO (32) heterotic string compacted on $B^0$ with a non-zero $H^0$-ux.

4.1. Mapping the parameters and couplings

Let us consider the orientifold of type IIB on $K3 \times T^2$ with a square $T^2$ by the action $(1)^F \mathbb{Z}_2$. The $\mathbb{Z}_2$ action sends $z^1 \rightarrow z^1$, where $z^1$ is the coordinate of the $T^2$. This compactification is a special point in the moduli space of F theory on $K3 \times K3$. Let the $T^2$ have sides of length $R_1$ and $R_2$, and volume $V = R_1 R_2$. We will take the $K3$ to have volume $e V$. At the orientifold point, the ten-dimensional string coupling is a free parameter which we will take to be $g_8$.

Two T-duality transformations along $T^2$ invert the radii in the usual way,

$$R_i' = \frac{1}{R_i};$$

where $i = 1;2$. The resulting type I theory has the following couplings and volumes:

$$g_1^{(4)} = g_8 = \frac{p}{V V}; \quad g_1^{(10)} = g_8 = \phi; \quad \phi_1 = 0 = \phi; \quad V_1 = V; \quad (4.1)$$

Here $g_1^{(4)}$ and $g_1^{(10)}$ denote the four and ten-dimensional couplings. The O7-planes and D7-branes are mapped to an O9 D9 system. If, for simplicity, we assume a trivial seven-brane gauge-field configuration over $K3$, then the initial gauge group is SO $(8)^4$. The gauge-field of the resulting O9 D9 theory then have non-trivial Wilson lines. Under a further S-duality transformation, we get the heterotic SO (32) theory. The resulting couplings and volumes can again be written in terms of IIB variables,

$$g_{het}^{(4)} = \frac{p}{g_8} = (V V); \quad g_{het}^{(10)} = \phi = (g_8 0); \quad \phi_{het} = 0 = g_8; \quad V_{het} = V \phi^2 = (g_8^2 0^2); \quad (4.2)$$

Our initial IIB supergravity description is valid in the limit where,

$$\phi = 0; \quad V = (0^2) >> 1; \quad (4.3)$$

If we want a weakly coupled orientifold theory, we can also take $g_8$ to be small but that is not necessary. Under condition $(4.3)$, both the heterotic and type I four-dimensional couplings can be made small. If $g_8$ is small, then an expansion of the resulting heterotic string theory is a good approximation.
4.2. The type IIB solution

To obtain the type IIB supergravity metric, we begin with M theory on $M = K^3_1 T^4 = \mathbb{Z}_2$. If we choose a smooth $K^3_1$ then our resulting type IIB metric will be smooth. We can also consider orbifold cases where $K^3_1 = T^4 = \mathbb{Z}_2$ where the metric is explicitly known. Otherwise, our resulting heterotic solution is given in terms of the metric of $K^3_1$. We will use coordinates $w^a$ for $K^3_1$. We again take $T^4 = T^2 \times T^2$ with coordinates $(z^1; z^2)$ and each factor square. Our initial M theory metric is then of the form (2.16) with $g$ the metric on $M$. We can choose to completely or partially cancel the anomaly with $G - \text{ux}$ satisfying,

$$\frac{1}{2} \zeta M \frac{G}{2} + \frac{G}{2} + n = 24;$$

Using arguments along the lines discussed in section 3, we can construct a $G$ with the form

$$\frac{G}{2} = \sum dz^1 dz^2 + \sum dz^1 dz^2 + \sum d\bar{z}^1 d\bar{z}^2 + \sum d\bar{z}^1 d\bar{z}^2;$$

(4.4)

where $2 H^{1,1}(K^3_1)$ and $2 H^{2,0}(K^3_1)$; Note that if $n = 0$, the model has $N = 2$ supersymmetry.

We treat the $z^2$ direction as the elliptic fiber, and lift this M theory vacuum to a type IIB orientifold of $K^3_1 T^2$. The resulting background fluxes are given by,

$$H = ( + )^* dz^1 + ( + )^* d\bar{z}^1$$

$$H^0 = ( + )^* dz^1 + ( + )^* d\bar{z}^1;$$

(4.5)

We note that $H$ and $H^0$ can be expressed in the form,

$$H = d + \sum dz^1 + \sum d\bar{z}^1$$

$$H^0 = d + \sum dz^1 + \sum d\bar{z}^1;$$

(4.6)

The potentials are not globally defined forms on the space $K^3_1 T^2$, but satisfy $d = 0$.

In string frame, the type IIB supergravity metric has the form:

$$0 \quad 0$$

$$g:$$

(4.7)

The indices $\quad ; = 0; \ldots ; 4$ and $g$ is the metric of $K^3_1 T^2 = \mathbb{Z}_2$. The warp factors and $\quad 0$ depend on the internal coordinates. We can determine $\quad 0$ in the following way.
Let us reduce from M theory to type IIA along a side of the elliptic fiber. The metric of the torus is warped,
\[ e^{-2dz^2dz^2} \]
The resulting type IIA metric in string frame is given by \([23]\),
\[ g_{\text{IIA}} = e^{-4G^{(10)}}; \]
where \(G^{(10)}\) is the straight dimensional reduction of the M theory metric. Using the metric \((2.16)\), we find that:
\[ = (0)^1 = e^3 = 4 : \]

Lastly, let us recall that the warp factor is determined by equation \((2.5)\). There are three source terms on the right hand side of this equation. Both the \(X_8\) curvature term and the membrane term are suppressed by six powers of \(M_{pl}\) relative to the \(G^G\) source term. To leading order in the derivative expansion, we can neglect the effect of both terms. With the form of \(G - ux\) given in \((4.4)\), the warp factor will have no dependence on \((z^1; z^2)\) at the level of the supergravity solution.

We can see this directly in type IIB supergravity. The only non-vanishing component of \(D^+\) is given by,
\[ D^+ = e^{3-2} : \]
The self-dual field strength \(F^+\) given in \((2.28)\) obeys \([23]\),
\[ dF^+ = H \wedge H^0 + (4^2) \frac{X^4}{64^2} \sum_{i=1}^2 \left[ \text{tr}(R^R)^2 (z^1 z_1^i) \right. \]
\[ + \sum_{j=1}^n \left. (z^1 z_j^i) (w w_j) \right]; \]
where \(z_1^i\) are the locations of the 07-plane plus four D7-branes, and \((z_j^i; w_j)\) are the locations of the D3-branes. From \((4.10)\), we obtain an equation for the warp factor:
\[ dD^+ = H \wedge H^0 + (4^2) \frac{X^4}{64^2} \sum_{i=1}^2 \left[ \text{tr}(R^R)^2 (z^1 z_1^i) \right. \]
\[ + \sum_{j=1}^n \left. (z^1 z_j^i) (w w_j) \right]; \]

\[ ^6 \text{It is worth noting that there is an obstruction to solving the warp factor equation \((2.5)\). However, if the anomaly cancellation condition \((1.2)\) is satisfied then the obstruction vanishes. The } X_8 \text{ and membrane terms are then crucial for ensuring the existence of a solution for the warp factor.} \]
Again the $H^\wedge H^0$ term is constant in $z^1$ while the remaining source terms are suppressed by powers of $0$.

4.3. Dualizing to a type I solution

To arrive at a type I solution, we $T$-dualize along both sides of the $T^2$ with coordinate $z^1 = x^1 + iy^1$. Using Buscher's duality [27] and [28, 29, 30], we can express the type I metric $g^I$ and RR two-form $B^0^I$ in terms of our initial type IIB quantities. Since $H$ and $H^0$ can be expressed in the form (4.6), we only have $B_{xa}^0; B_{xa}^0$ and $B_{ya}^0; B_{ya}^0$ components. The type I metric is then given by

$$g^I_{ab} = g_{ab} + \frac{1}{g_{xx}} B_{xa} B_{xb} + \frac{1}{g_{yy}} B_{ya} B_{yb};$$

$$g^I_{xa} = \frac{1}{g_{xx}} B_{xa}; \quad g^I_{ya} = \frac{1}{g_{yy}} B_{ya};$$

$$g^I_{xx} = \frac{1}{g_{xx}}; \quad g^I_{yy} = \frac{1}{g_{yy}}; \quad g^I_{xy} = 0;$$

where the $a; b$ directions are along $K 3_1$. The type I dilaton is inversely proportional to the warp factor:

$$e^I = \frac{g_{aa}}{g_{xx} g_{yy}}:$$

The $B^0^I$-eld is given by,

$$B^0^I_{ab} = \frac{3}{2} \sum_{[a [B_{by}^0 \wedge B_{xa}^0 \wedge B_{by}^0] + 2B_{xa}^0 B_{by}^0;i}$$

$$B^0^I_{xa} = B_{ya}^0; \quad B^0^I_{ya} = B_{ax}^0; \quad B^0^I_{xy} = 0;$$

Note that we have used the fact that $D^+ has no internal components in the above expressions. If we set either or to zero in (4.5), then one can check using the local expressions (4.6) for $B$ and $B^0$ that $B^0_{ab} = 0$.

Using coordinates $w^a$ for $K 3_1$, we can rewrite the type I metric in a way that makes the structure a little clearer:

$$ds^2 = g_{ab} dw^a dw^b + \frac{1}{g_{xx}} (dx + B_{xa} dw^a)^2 + \frac{1}{g_{yy}} (dy + B_{ya} dw^a)^2;$$

The $T^2$ parametrized by $x$ and $y$ is now non-trivially twisted over the base $K 3_1$. By viewing $B_{xa} dw^a$ and $B_{ya} dw^a$ as Kaluza-Klein gauge-elds, we see that the twisting is encoded in the characteristic classes of these gauge-elds on $K 3_1$.

---

We set $4^2 0 = 1$ for the remainder of the paper.
Since T-duality is a perturbative symmetry, we have arrived at a consistent type I background (4.12), (4.13) and (4.14). We can S-dualize to a perturbative heterotic compactification with dilaton,
\[ e^{\text{het}} = \frac{1}{g_s} P \frac{1}{g_{\alpha \beta} g_{\gamma \delta}} ; \]  
(4.16)
and string frame metric:
\[ \frac{1}{g_s} P \frac{1}{g_{\alpha \beta} g_{\gamma \delta}} 0 0 \]  
(4.17)
Under S-duality, \( B^0 \) ! \( B^{\text{het}} \).

Torsional string compactifications satisfy a number of stringent constraints. See [31, 32, 33, 34, 35] for a discussion of various aspects of torsional compactifications. As a nal comment, we note that since our torsional vacuum is T-dual to an anomaly free orientifold, we can infer a great deal about the resulting metric and B - field. Our space should have trivial rst Chern class. Since no SO (32) gauge - fields are excited, \( p_1 (B^0) \) must also be trivial in cohomology to satisfy the usual anomaly cancellation condition,
\[ dH^{\text{het}} = \text{tr} (R^\wedge R) = \frac{1}{30} \text{tr} (F^\wedge F) ; \]

This is not as plausible as it might rst seem. In the \( E_8 \times E_8 \) heterotic dual to the original type IIB orientifold, \( p_1 (K3) \) is cancelled by embedding instantons in some abelian gauge- fields. It seems reasonable that the instantons in the Kaluza-Klein gauge - fields \( B_{x^a} dw^a \) and \( B_{y^a} dw^a \) could analogously cancel \( p_1 (K3) \) in this case. Finally, it should be possible to show that the metric (4.17) and \( H^{\text{het}} \) are derivable from a real prepotential, analogous to the Kahler potential [31].

Acknowledgments

It is our pleasure to thank S. Mukhi for early participation, and D. R. Morrison for late participation in this project. We are particularly grateful to D. E. Diaconescu and D. R. M. for numerous suggestions and comments. We have also been aided by conversations with L. Gottsche, Z. Kakushadze, A. Klemm, M. Rocek, A. Sen and E. Witten. The work of K. D. is supported in part by DOE Grant No. DE-FG-02-90-ER40542. The work of R. C. is supported in part by NSF Grant No. DM S-9627351 and by NSF Grant No. PHY 94-07194, while that of S. S. is supported by the William Keck Foundation and by NSF grant No. PHY (9513835).
