Abstract

We analyze the finite temperature deco\(\text{n}\)ning phase transition in 2+1 dimensional Georgi-
Glashow model. We show explicitly that the transition is due to the restoration of the
magnetic \(Z_2\) symmetry and that it is in the Ising universality class. We find that neglecting
effects of the charged \(W\) bosons leads to incorrect predictions for the value of the critical
temperature and the universality class of the transition, as well as for various correlation
functions in the high temperature phase. We derive the effective action for the Polyakov
loop in the high temperature phase and calculate the correlation functions of magnetic
vortex operators.

1 Introduction

The deconfining phase transition in QCD has been a subject of numerous studies in recent years. Some aspects of the physics of the high temperature phase appear to be perturbative and can be studied in a controlled way at asymptotically high temperatures. However, in the phase transition region itself the QCD coupling is large and the physics is dominated by the nonperturbative soft sector. Analytic understanding of this region is therefore extremely difficult. It thus seems useful to find a simpler toy model, where a similar deconfining phase transition is within the weak coupling regime and can be studied analytically. Optimistically one can hope to learn some lessons from such a model which could be of use in our understanding of real life QCD.

A model that is very suitable for this purpose is the Georgi-Glashow model in 2+1 dimensions—Yang-Mills theory with a Higgs field in the adjoint representation. Over twenty years ago Polychok [1] showed that in this theory the instantons (monopoles) dominate the nonperturbative dynamics and disorder the Higgs vacuum, leading to a linear confinement of electric charges even at arbitrarily weak coupling. This was the first demonstration of the dual Meissner effect (or dual superconductivity) in a non-Abelian gauge theory where monopoles condense and expel electric fields from the vacuum, providing an example of the enigmatic confinement phenomenon in controllable circumstances. At zero temperature the 3D Yang-Mills-Higgs system is therefore always in the conning phase, even though classically the conning and Higgs regimes appear to be separated by a phase transition.

In this paper we will study the theory at finite temperature with particular emphasis on the deconfining phase transition. We note that a similar study appeared in the literature several years ago [2]. Our results are both qualitatively and quantitatively different from those of [2]. In particular we show that the deconfining phase transition is primarily due to the plasma effects of charged excitations (W bosons), an effect that was neglected completely in the analysis of [2]. As a result our predictions for both the value of the critical temperature and the universality class of the phase transition are different.

The structure of this paper is the following. In section 2 we review the model and discuss the two complementary views of the confinement mechanism: one based on the
monopole plasma \[1\] and the other based on vortex condensation \[3,4\]. In section 3 we discuss the naive expectations for the deconfinement phase transition which follow from these two approaches. We show that these expectations are different and explain why the monopole plasma intuition (the basis of the approach of \[3\]) should be refined in order to discuss the phase transition properly. In section 4 we describe the renormalization group analysis of the phase transition. We determine the value of the critical temperature, the universality class and discuss the crucial role played by the electrically charged particles. In section 5 we relate our analysis to the standard tool used in the high temperature phase - the effective potential for the Polyakov line. We derive this effective potential in the deconfining phase and show with its help explicitly that the correlation function of vortex operators at \(T > T_c\) decreases exponentially at large distances and thus that the magnetic \(Z_2\) symmetry is restored. Finally in section 6 we discuss briefly our results.

2 The model

We consider the SU(2) gauge theory with a scalar field in the adjoint representation in 2+1 dimensions.

\[
S = \frac{1}{2g^2} \int d^3x (F^a F_a) + \int d^3x \left( \frac{1}{2} (D^a h^a)^2 + \frac{1}{4} (h^a h^a v^2) \right)
\]  

(1)

We adopt the notation \(A = \frac{i}{2} A^a_a\), \(F = @ A - @ A + [A ; A]\), \(h = \frac{i}{2} h^a_a\), and \(D = @ + [A ; h]\) and the trace is normalized as \(\text{tr}(A^a_b) = 2\). We will be interested throughout this paper in the weakly coupled regime \(v^2 = g^2\). In this regime perturbatively the gauge group is broken to U(1) by the large expectation value of the Higgs field. The photon associated with the unbroken subgroup is massless whereas the Higgs and the other two gauge bosons \(W\) are heavy with the masses

\[
M^2_H = 2v^2; \quad M^2_W = g^2v^2.
\]  

(2)

Thus perturbatively the theory behaves very much like electrodynamics with spin one charged matter. The nonperturbative effects however are very important at large distances. Their effect is that the photon acquires finite mass and the charged \(W\) become linearly confined at large distances with nonperturbatively small string tension.
2.1 The monopole plasma

The nonperturbative configurations that dominate the generating functional in the weakly coupled regime are solutions to the classical Euclidean equations of motion,

\[ D F = [h; \begin{array}{c} D h \end{array}] ; \]

\[ D D h = (\hat{\Phi} h^a \hat{\nabla}^2) h = 0. \tag{3} \]

The perturbative vacuum manifold is $SO(3) \rightarrow U(1)$ and this has a nonzero second homotopy group, $\pi_2(SO(3) \rightarrow U(1)) = \mathbb{Z}$. The theory thus allows topologically non-trivial solutions. Polyakov showed \[1\] that, in the vacuum only far separated monopole configurations are relevant. The unit charge configuration is of the well-known 't Hooft-Polyakov monopole form,

\[ h^a(x) = x^a h(r) \]

\[ A^a(x) = \frac{1}{r} \left[ a \times (1 \ 1) + a \times (r A \ 2) \right] \tag{4} \]

where $x^a = x^a = r$. The non-Abelian field strength is

\[ F^a = \frac{1}{r^2} a^a x^b \frac{1}{2} (\begin{array}{c} 2 \ 2 \ 1 \\
\end{array}) + \frac{1}{r} (a \times a) \frac{1}{r} (0 \ 1 + A \ 2) \]

\[ + (a \times a \times a) \frac{1}{r} (0 \ 2 + A \ 1); \tag{5} \]

where prime denotes differentiation with respect to 3D radial coordinate $r$. The nilpotency of the action (in the gauge $A = 2 = 0$) requires $h(0) = 0$, $h(1) = v$, $1(0) = 1$, and $1(1) = 0$.

The monopole has a core size of the order of the vector meson mass. Outside the monopole core, the theory is Abelian and one can define the Abelian field strength as,

\[ F = \frac{h^a}{h} F^a = \frac{1}{h^3} a^b h^a (D^b h)^c (D^c h)^c; \tag{6} \]

The monopoles (instantons) interact via a Coulomb potential in the Euclidean three dimensional sense, and the partition function of the Coulomb gas can be written as a path integral over the dual photon field. The effective Lagrangian for the field reads

\[ L_{\text{eff}} = \frac{g^2}{32} (\vec{\Phi} \ 2^2 + \frac{M^2 g^2}{16} \cos \theta; \tag{7} \]
The dynamically generated photon mass, due to the Debye screening of the monopoles, is given in terms of the fugacity of the monopoles as

\[ M^2 = \frac{16}{g^2} \]

\[ = \text{constant} \frac{M_W^{7/2}}{g} e^{-\frac{g}{4} \frac{M_W}{M_W^*}} \]  

(8)

(\( M_W^* \)) is such that \( 1 : 78 \) [5], and \( (1 : 1) = 1 \). The field is by far the lightest excitation in the theory and thus eq. (1) is the low energy effective Lagrangian of the theory valid below the energy scale \( M_W \). The fundamental Wilson loop calculated in this effective theory [3] has an area law falloff, indicating confinement.

2.2 The vortex condensation

A complementary view of confinement in this theory is the spontaneous breaking of the magnetic \( Z_2 \) symmetry due to the condensation of magnetic vortices [3].

Ignoring monopole effects, the model has the magnetic \( U(1) \) symmetry generated by the Abelian magnetic field. The conserved current is the dual field strength

\[ F^* = \frac{1}{4} F^* \]  

(9)

As discussed in detail in [1], due to the monopole contributions, this symmetry is anomalous, and only the \( Z_2 \) subgroup is conserved. The non-anomalous \( Z_2 \) magnetic symmetry group is generated [3] by the large spatial Wilson loop which encloses the system

\[ W(C \times 1) = \exp \frac{i}{2} \int d^2 x B(x) \]  

(10)

The order parameter for this \( Z_2 \) transformation is the operator that creates an elementary magnetic vortex of \( \nu = 2 \) [3, 4]

\[ V(x) = \exp \frac{2}{g} \int \frac{i Z}{ \frac{h}{c} \hat{h}} E^a_j(x) \]  

(11)

This operator is local, gauge invariant and Lorentz scalar. Together with the spatial Wilson loop it forms the order-disorder algebra

\[ W(C \times 1) V(x) = V(x) W(C \times 1) \]  

(12)
It can be shown [4] that the vortex operator condenses in the vacuum and its expectation value is determined by the gauge coupling constant $<V> = g^2 = 8^2$. The low energy theory from this point of view is given by the $Z_2$ invariant theory of the vortex field $V$

$$L_e = \partial V \partial V + \left(\frac{g^2}{8}V^2\right)^2 + \frac{M^2}{4} V^2 + (V^2)^2 g^2$$

(13)

The vortex self-coupling in this effective Lagrangian can be determined as [3]

$$= \frac{2^2 M^2}{g^2}$$

(14)

Note that as a low energy Lagrangian, eq. (13) is indeed consistent with eq. (7). At weak gauge coupling the quartic coupling is very large. In this nonlinear $-m$odel limit the radius of the field $V$ is therefore frozen to its expectation value. The only relevant degree of freedom is the phase

$$V(x) = \frac{g}{8} e^{i}$$

(15)

Substituting this into eq. (13) one indeed obtains precisely eq. (7) with the identification $= 2$. It was shown in [4] that this identification is indeed the correct one, and the factor 2 follows from the fact that the magnetic charge of the monopole is twice the fundamental value relative to the electric charge of the elementary charged excitation $W$ : $g_m g_e = 4$.

The main difference between eq. (13) and eq. (7) is in the description of the charged sector. As explained in [4], the charged particles are solitons of the field $V$ with unit winding number. In the nonlinear $-m$odel limit those are just vortices of the phase $V$. Polyakov’s effective Lagrangian eq. (7) does not allow such vortex configurations. In the vortex configuration the field (and ) is discontinuous along an infinite cut. The cut contributes to the kinetic energy term in eq. (7), and this contribution is both ultraviolet and infrared divergent. The ultraviolet divergence is of no importance by itself, since the theory is defined with the intrinsic $UV$ cutoff $M_W$. However the infrared divergence indisputably puts description of the charged states beyond eq. (7). On the other hand eq. (13) recognizes the fact that the field is a phase, and therefore 2 discontinuities in it are unphysical and do not cost energy. Thus vortex configurations in eq. (13) are allowed.
Although they are connected dynamically with a linear potential \[ V(x) \], the string tension for this potential is a dynamical effect proportional to \( g^2 \) and has nothing to do with the extraneous cut contribution.

In fact, if anything the Lagrangian eq. (13) underestimates the energy of such a vortex. The core energy of the vortex should be equal to the mass of the charged vector boson \( M_W \), since this is the lightest charged excitation in the theory. On the other hand the core mass of a vortex in the Lagrangian eq. (13) is given by the UV contribution of the Coulomb potential. With the cut off of order \( M_W \) this is of order \( g^2 \ln M_W = g^2 \). This is not surprising, since the mass of the \( W^- \) boson indeed comes from the distances of order of its Compton wavelength, and is thus well inside the UV cut off of the effective theory. The situation can be improved by adding to the effective Lagrangian a higher derivative term of the Skyrme type

\[
L = (\partial V \partial V)^2
\]

with

\[
/ \frac{1}{g^4 M_W}
\]

With this extra term the core energy of the vortex indeed becomes of the order of \( M_W \).

As we will see in the following, the correct description of the charged sector is crucial for the understanding of the phase transition\[5\].

3 Deconfining phase transition - The Rough Guide

In this section we give a naive discussion of the expected nature of the deconfining phase transition based on the monopole versus vortex description of the low energy theory.

\[5\] We note that this is not the only instance in which the charged states play a prominent role. For example as discussed in \[3\] the presence of these states leads to the breaking of the string of charge two, which in the Polyakov's effective Lagrangian eq.\[4\] is strictly stable.
3.1 The monopole binding

Since at zero temperature the monopole contributions are the only relevant ones for confinement, one may be tempted to assume that also at finite, low enough temperature all other effects are not important. The expected value of the transition temperature, as we shall see in a moment, is of order $g^2$, which is much smaller than any mass scale in the theory except for the photon mass. One could therefore start with the working hypothesis that the single self-interacting photon field (or equivalently the monopole ensemble) should be a valid description of the phase transition region. This is the point of view taken in [2], and we now briefly describe the conclusions it leads to.

The first thing to note is that at finite temperature the interaction between monopoles is logarithmic at large distances. The reason is that the finite temperature path integral is formulated with periodic boundary conditions in the Euclidean temperature direction. The field lines are therefore prevented from crossing the boundary in this direction. The magnetic field lines emanating from the monopole have to bend close to the boundary and go parallel to it. So effectively the whole magnetic flux is squeezed into two dimensions. Qualitatively the situation is shown in Figure 1.

![Figure 1: The field of a Monopole-Instanton at finite temperature.](image)

The length of the time direction is $\frac{1}{T}$, and thus clearly the field profile is two dimensional on distance scales larger than $\frac{1}{T}$. Two monopoles separated by a distance larger than therefore interact via a two-dimensional rather than a three-dimensional Coulomb potential, which is logarithmic at large distances. Since the density of the monopoles is tiny $m^2 T$ at extremely low temperatures $T < \frac{1}{e^2}$ the monopole gas becomes...
two dimensional. The strength of the logarithmic interaction is easily calculated. The magnetic flux of the monopole should spread evenly in the compact direction once we are far enough from the monopole core. The field strength should have only components parallel to the spatial directions. Since the total flux of the monopole is \( 2 = g \), the field strength far from the core is \( F_i = \frac{I_i}{g} x_i \), and thus the strength of the infrared logarithmic interaction is \( T^2 = g^2 \).

It is well known \([7]\) that the two dimensional Coulomb gas undergoes the BKT phase transition. In the usual Coulomb gas, where the strength of the interaction does not depend on temperature, the particles are bound in pairs at low temperature and unbind at high temperature \( T > T_{BKT} = 2 \), where the entropy overcomes the energy. This is the standard BKT phase transition \([7]\) which determines the universality class of \( U(1) \) symmetry restoration in 2 dimensions. In the present case the situation is reversed, since the strength of the interaction itself depends on the temperature. At low temperature the interaction is weak, and therefore the particles (monopoles) are free. As the temperature grows, the interaction becomes stronger until at \( T_{BKT} = 2 \frac{T_{BKT}}{g^2} \) the energy overcomes the entropy. Above this temperature the monopoles bind into neutral pairs. Thus based on this simple picture we expect the theory to undergo a BKT phase transition at

\[
T_{BKT} = g^2 \frac{2}{2} \quad (18)
\]

Below this temperature the photon should be massive, while above this temperature it should be massless since the cosine term in the Lagrangian eq. \((19)\) is irrelevant.

This is precisely the logic followed in \([2]\). One can go further and perform more quantitative calculations using the dimensionally reduced Polyakov effective Lagrangian. Dimensional reduction should be perfectly valid in this theory since the critical temperature is much larger than the photon mass. Thus one can consider the two dimensional sine-Gordon theory

\[
L = \frac{g^2}{32} \left( \frac{\partial \phi}{\partial t} \right)^2 + \frac{M^2 g^2}{16} \cos^2 \quad (19)
\]

This theory, in full agreement with the previous discussion has a BKT phase transition at
the temperature given by eq. (13), above which the "dual photon" field becomes massless.

Moreover, since the 2-d sine-Gordon theory is exactly solvable, one can calculate various correlation functions. In particular the authors of [2] calculated the string tension, and found that it exhibits quite strange behavior. At low temperatures it follows an expected pattern — that is, it decreases with temperature. It becomes extremely small at temperature much smaller than \( T_{\text{BK T}} \); however just before \( T_{\text{BK T}} \) it starts rising sharply and at \( T_{\text{BK T}} \) actually diverges.

Although the logic leading to the previous discussion seems quite sound, there are several puzzles that arise regarding the results.

The photon becomes massless in the high temperature phase. In other words, the correlation length in some physical (gauge invariant) channel becomes infinite at high temperature. This contradicts our physical intuition, since one expects that at high temperature any physical system described by a local field theory should become maximally disordered with zero correlation length.

The phase transition is of BKT type, and therefore belongs to the U(1) universality class. On the other hand we know that the global symmetry that is restored at the phase transition is the magnetic \( Z_2 \) [8], and we expect the universality class to be 2D Ising.

The divergence of the string tension at the critical point looks unphysical.

Finally, as we explained in the previous section, the effective theory eq.(7) does not allow charged states. It is then difficult to understand in what sense the high temperature phase can be viewed as deconfined.

3.2 Magnetic symmetry restoration and the charged plasma

Let us now take eq. (13) as our starting point. What does one expect from the phase transition in a simple scalar theory of this type? Firstly, clearly one expects the critical temperature to be of order of the expectation value of the scalar field, and therefore parametrically of order \( g^2 \). At finite temperature one expects the generation of a positive effective mass proportional to the temperature and to the coupling constant. Thus the
them all contribution to the effective potential should be of the form

$$\tau L = xTVV$$  \hspace{1cm} (20)$$

At $T = g^2 = 4.2x$ the total monopole term becomes positive, the VEV of $V$ vanishes and the phase transition occurs. One can estimate this temperature more precisely using the following simple argument. Let us neglect for now the monopole induced term. Then we are dealing with the XY model at finite temperature. The dimensional reduction should again be a valid approximation, and thus essentially we have to analyze a 2D model. Now a 2D XY model can be mapped into a sine-Gordon theory of a dual field $\sim$. Performing this dual transformation\[6\], we find the Lagrangian

$$L = \frac{T}{2g^2}(\theta_1 \sim)^2 + \cos \sim$$  \hspace{1cm} (21)$$

where $\sim$ is the fugacity of the vortices in the XY model. This sine-Gordon theory has a phase transition at

$$T_{XY} = \frac{g^2}{8};$$  \hspace{1cm} (22)$$

Therefore we may expect the magnetic symmetry restoring phase transition at $T_{XY}$. Although parametrically this temperature is of the same order as the BKT transition temperature discussed in the previous subsection, it is four times lower. Another important difference is that the nature of the phase transition is in fact completely different. The phase transition in the model eq. (21) is due to the unbinding of vortices of the field $V$. Above $T_{XY}$ the vortices are in the plasma phase. These vortices, are as discussed earlier precisely the charged $W$ bosons of the original Georgi-Glashow model. Thus this phase transition is just what one would naturally call the deconfining phase transition and the vacuum above $T_{XY}$ is the charged plasma.

Note that in this discussion we have neglected completely the effect of monopoles, that is the last term in the Lagrangian eq. (13). Interestingly enough we see that the plasma
phase is reached at a temperature which is much lower than the $T_{BK}$ discussed earlier, and thus the monopole binding is irrelevant for the dynamics of the deconfinement. This is not to say that the presence of the monopoles is irrelevant altogether. Clearly, omitting the monopole induced term we enlarged the symmetry of the system from $Z_2$ to $U(1)$. Hence the effective $XY$ model description and the $U(1)$ universality class predicted by eq. (21).

The analysis as it stands is correct for noncompact electrodynamics with charged matter, but not for the Georgi-Glashow model. Next we remedy this problem.

The effect of the monopoles can be qualitatively understood in a simple way. Their presence leads to a confining potential between the charges, that is a linear interaction between the $XY$ model vortices. Thus the monopoles suppress the variation of the phase of the field $\mathcal{V}$ except inside the confining string, the width of which is given by the inverse photon mass $d = M_\gamma / \rho$. Whether the presence of the monopoles is important at the \textit{would be} phase transition point $T_{XY}$ depends crucially on the density of charged particles. If the density of the charged particles is very high, so that the average distance between them is smaller than $d$, the presence of the monopoles is immaterial since the phase of $\mathcal{V}$ is disordered already on the short distance scale. However if the density of charges is low, so that the distance between them is larger than $d$, the presence of the monopoles will suppress the phase transition. In this case at $T_{XY}$ the vacuum will not be disordered, but will look like a dilute gas of charged particles with strings between them. The actual phase transition will then occur at a higher temperature, where the average distance between the charges equals the inverse photon mass.

Interestingly enough in the present case this temperature turns out to be twice the value of $T_{XY}$ and therefore still much lower than $T_{BK}$. We will show this rigorously in the next section. Qualitatively though this is easy to understand. The density of charges is proportional to their fugacity

$$\rho \propto \frac{M_\gamma}{e^{\frac{\mu}{T}}},$$

(23)

This should be compared to the square of the photon mass, which is given by the zero
tem perature monopole fugacity. In a theory with very heavy Higgs
\[
\frac{\Gamma_m}{e^{4\pi\alpha_{em}}}
\]  
(24)

The two are equal (up to subleading corrections) at
\[
T_{GG} = \frac{g^2}{4}
\]  
(25)

More generally, when the Higgs is not in nite heavy, the monopole fugacity is smaller and thus the transition temperature will be lower
\[
T_c = \frac{g^2}{4} \left(\frac{M^2}{\lambda}\right)
\]  
(26)

For lighter Higgs, \(T_c\) gets closer to \(T_{XY}\), but is always greater so that \(T_{XY} < T_c < T_{BK}\).

In the next section we will present a more complete analysis based on the renormalization group and exact bosonization. This analysis con rms the simple picture presented here. Thus all the puzzles raised in the previous subsection simply disappear.

The photon never becomes massless. Even without the monopoles in the plasma phase it acquires the Debye mass given by the cosine term in eq. (21). This mass rises with temperature, and thus the physical correlation length decreases.

Since the monopole term is still relevant at the phase transition, the universality class must be \(Z_2\). We will see this explicitly in the next section.

The analysis of the previous subsection is only valid below \(T_Y\), and thus the divergence of the string tension at \(T_{BK} > T_{XY}\) has nothing to do with the physics of the GeorgiGlashow model.

Finally, the phase transition is driven primarily by the unbinding of charged particles and thus indeed has all theavor of a decon nection transition.

Let us now turn to a more quantitative analysis of what is stated above.

4 Decon nection phase transition - renormalization group analysis

For a more formal analysis of the phase transition we nd it convenient to use the sine-Gordon formulation in terms of the phase field modified to take explicitly into account
the finite probability of the appearance of vortices. This Lagrangian has the form

$$L = \frac{g^2}{8} \left[ \phi \right]^2 + \cos^2 \phi + \cos \theta \sim$$  \hspace{1cm} (27)

where is related to the monopole fugacity $= T$ and $\sim$ is the field dual to ,

$$i\phi \sim = \frac{g^2}{2} \theta \quad :$$  \hspace{1cm} (28)

4.1 The Lagrangian

The way to derive this Lagrangian is the following. The partition function of the sine-Gordon model in the presence of one vortex is

$$Z(x) = \int \exp \left[ \int \frac{g^2}{8} \left[ \phi \right]^2 \theta \left( j(y;x) \right)^2 + \cos^2 \phi \right]$$  \hspace{1cm} (29)

The \textit{external current} is

$$j(y;x) = 2 \, n(y) \, (y \, 2 \, C)$$  \hspace{1cm} (30)

with $C$ a curve that starts at the location of the vortex (the point $x$), and goes to infinity, and $n$ is the unit normal to this curve. The insertion of this current forces the derivative of to have a discontinuity across the curve $C$, so that jumps by 2. This forces to have one unit of vorticity concentrated at the point $x$. Note that even though $j$ explicitly depends on the curve $C$, the partition function itself does not, since changing the integration variable

$$(x) \rightarrow (x) + 2 \quad ; \quad x \, 2 \, S$$  \hspace{1cm} (31)

where the boundary of $S$ is $C$. $C^0$ is equivalent to changing $C$ into $C^0$ in the definition of the current. The extra linear term in the exponential in (eq.29) is

$$i\sim = \frac{g^2}{2} \int \frac{Z}{T} \, dx \quad \theta :$$  \hspace{1cm} (32)

which is equivalent to (eq.28). An antivortex at $y$ obviously is created by $j$. To create several vortices one just inserts an external current which is the sum of the currents which create individual vortices.
A dilute ensemble of vortices and antivortices with (small) fugacity is then given by

\[ Z = \prod_{n,m} \frac{1}{n!m!} Z^{n+m} \int dx_i \int dy_j Z(x_i; y_j) \]  \hspace{1cm} (33)

The summation over the number of vortices and antivortices can be easily performed leading to the partition function with the Lagrangian eq. (27). The constant is the vortex fugacity scaled by the effective UV cut imposed on the integration over the coordinates. The vortex fugacity of course is none other but the fugacity of the charged W,

\[ = a^2 e^{-\frac{W}{T}} \]  \hspace{1cm} (34)

The cut is related to the Compton wave length of the W boson, but a more careful determination of it should take into account the fact that in the process of dimensional reduction all modes with frequencies above T have been integrated out. We will not attempt the determination of a, but only note that it is some combination of the scales M_W and T/g^2, and as such its value always plays a role secondary to the exponential factor of fugacity [7].

An alternative way to derive the Lagrangian eq. (27) is to start directly from the effective theory eq. (13) with the extra Skyrme term eq. (16). In the nonlinear -model limit one can cleanly separate the phase of the field V into a smooth part and the vortex contribution. The Skyrme term then is proportional to the energy of one vortex, and with the Skyrme coupling chosen the way we discussed in Section 2 is just equal to M_W for a one vortex configuration. The dilute vortex gas approximation then reproduces again the Lagrangian eq. (27).

4.2 The renormalization group equations

Our starting point for the discussion of this section is eq. (27). Since both and are small, the importance of different terms in the Lagrangian is determined by their respective

For the same reason the effective value of the monopole induced mass also changes in the dimensionally reduced theory. This change has been calculated in [7]. Again we will not dwell on this "nice renormalization" since this effect is subleading in the same sense.
confomal dimensions calculated in the free theory. The total confomal dimensions of the
operators: \( \cos^2 \), \( \cos \), respectively are,

\[
\begin{align*}
\mathcal{D}(\cos^2) &= 4 \frac{T}{g^2}; \\
\mathcal{D}(\cos) &= \frac{g^2}{4} T;
\end{align*}
\]  

Thus at low temperature the charges are irrelevant (\( g^2 > 2 \)) and the monopoles are
relevant (\( g^2 < 2 \)) and the theory reduces to the sine-Gordon model. At the temperature
\( T = g^2 = 4 \) the two operators become equally relevant since their confomal dimensions are
equal

\[
\mathcal{D}(\cos^2) = \mathcal{D}(\cos) = 1;
\]  

The phase transition point can be determined from the structure of the xed points
of the renormalization group equations. The critical point is the IR unstable xed point
of the RG flow. The renormalization group equations of the sine-Gordon theory have been
studied perturbatively in the literature both in the absence \([10]\) and in the presence of the
vortices \([11]\). In terms of the dimensionless parameters

\[
t = \frac{4}{g^2} T; \quad \sim = a^2; \quad \tilde{\sim} = \tilde{a};
\]

the lowest order RG equations read

\[
\begin{align*}
\frac{d t}{d} &= 2 (\sim^2 - \tilde{\sim}^2); \\
\frac{d \sim}{d} &= (2 \frac{1}{t}) \sim; \\
\frac{d \tilde{\sim}}{d} &= (2 t) \tilde{\sim};
\end{align*}
\]  

The xed point structure of these equations is simple.

1. The point \( T_0 \)

\[
t = 0; \quad \sim = 0; \quad \tilde{\sim} = 1
\]  

is clearly the zero temperature xed point. Here the long distance physics is dominated by
the monopole induced mass term.
2. The point $T_1$

$$\begin{align*}
t &= 1; \quad \sim &= 1; \quad \sim &= 0 \quad (42)
\end{align*}$$

is the high temperature fixed point. Here the infrared properties are determined by the charged plasma effects.

3. The point $T_{GG}$

$$\begin{align*}
t &= 1; \quad \sim &= \sim; \quad \sim &= 1 \quad (43)
\end{align*}$$

This is the IR unstable fixed point. This is precisely the critical point that corresponds to the deconfining phase transition. At this point both the monopole and the charge plasma induced terms are equally important.

Note that the fixed line $t > 2; \sim = 0$ of massless theories which corresponds to the \textit{con ned monopole plasma} is not present, since for $t > 2$ the charged plasma induced mass term is strongly relevant. The same is true for the would be fixed line $t < 1=2; \sim = 0$, which is present in the absence of the monopoles and describes the low temperature massless phase of noncompact electrodynamics.

It is instructive to see how the RG equations formalize our qualitative arguments of the previous section. In particular they make clear the role of the point $t = 1=2$ which in the absence of monopoles would be the point where the charged induced term becomes relevant. If one starts the evolution from the initial condition $t = 1=2, \sim, \sim$, the running temperature will increase, and $\sim$ will grow into the infrared, while $\sim$ will grow for a while until the running temperature reaches two. From this point on $\sim$ will decrease and the system will approach the high temperature fixed point. This corresponds to the situation where at the \textit{would be} critical point $t = 1=2$ the density of charged plasma is so high that the mean distance between the particles is smaller than the width of the confining string.

On the other hand if the initial condition is $\sim < \sim$, the temperature starts decreasing, making the coupling $\sim$ immediately irrelevant. Thus $\sim$ monotonically decreases to zero and practically does not affect the ow of the other couplings which steadily ow to the
zero tem perature xed point. This is the situation where at t = 1=2 the density of charged plasma is low, which is indeed true in our model.

Interestingly enough, at t = 1 the initial conditions in our model in the case of very heavy Higgs are such that the RG ow starts almost exactly in the region of attraction of the xed point TGG. At this value of temperature the monopole and charge fugacities are equal. The only difference between ~ and ~ then is in the prefactors, which are possibly different combinations of MW and g2. If ~ and ~ were exactly equal, the only thing that happens along the ow is that their values grow, but t does not change. Due to the small difference their values are equal at a temperature which slightly differs from 1

\[ \frac{M_W}{T} = \frac{4 M_W}{g^2} + \mathcal{O}(1); \quad T = \frac{g^2}{4} \left[ 1 + \mathcal{O} \left( \frac{g^2}{M_W} \right) \right] \] (44)

Thus the initial temperature for which the system is in the region of attraction of TGG is slightly different. We conclude that the critical temperature of the Georgi-Glashow model is indeed, up to corrections of order g2=MW, given by TGG = \frac{g^2}{4}.

A comment is in order about our use of the perturbative renormalization group equations. As written the equations (44) are only valid for small ~ and ~. The initial values of these constants in our model are indeed small, and thus the ow is well described by these equations for quite a while. The xed points however correspond to large values of at least some parameters, and thus quantitative details of the ow in this region of parameter space are different. However the existence of the three xed points T0, T1 and TGG is an exact statement. For T0 and T1 this is a consequence of the fact that one of the couplings vanishes (~ or ~) and thus these xed points are the same as in the corresponding sine-Gordon theory. The existence of TGG is a consequence of the exact duality in the model eq. (27). The transformation 2 t ! ~ in the path integral leads to the same partition function but with new parameters as follows: t ! ~, ~ ! ~. This symmetry is nothing but the famous T-duality (see for example [12] and references therein). The point TGG of the exact renormalization group equations.
4.3 The universality class of the phase transition

Since the deconfining phase transition is due to the restoration of $Z_2$ symmetry we expect that it is in the 2-dimensional Ising universality class. This can be shown exactly by studying the theory eq. (27) at the fixed point $t = 1$. The following discussion follows closely [13] [See also chapter 21 in [14]].

The theory described by eq. (27) can be fermionized by using the standard bosonization/ferm ionization technique. Since at $t = 1$ both cosine terms have dimension 1, the resulting fermionic theory is a theory of free massive fermions. In our notations, the Dirac fermionic field is defined as

$$ R = a_1 \exp \left[ i \left( + \frac{\pi}{2} \right) \right]; \quad L = a_1 \exp \left[ i \left( - \frac{\pi}{2} \right) \right]; \quad (45) $$

The kinetic term in eq. (27) then becomes the kinetic term of the field, while the cosine terms become

$$ R \cos 2 \pi = i \left[ R, L \right] \chi; \quad \chi $$
$$ L \cos \pi = i \left[ R, L \right] \chi; \quad (46) $$

Thus the mass term in the fermionized Lagrangian is diagonalized by introducing the real Majorana fermions

$$ \phi = \frac{R + L}{2}; \quad \bar{\phi} = \frac{R - L}{2}; \quad (47) $$

The mass of the fermion is $a + a$, while the mass of is $a \cdot a$. For $t = 1$ the model contains one massive and one massless fermion. At the fixed point $t = 1$ the massive fermion decouples. Thus at the point $T_{GG}$ the theory is of one massless Majorana fermion. It is well known that this theory precisely describes the critical point of the 2D Ising model.

Thus we indeed see that the phase transition is in the universality class of the 2D Ising model.
5 From the magnetic vortices to the Polyakov line

It is standard practice to study the high temperature phase of gauge field theories using the effective action in terms of the zeroth component of the vector potential $A_0$. In this section we want to relate our analysis which was performed for the phase of the vortex operator to this standard procedure.

The relation in fact is not difficult to make. The free energy of the charged $W$ bosons in the Lagrangian eq. [21] is given by the term $\cos \sim$. On the other hand this same free energy in the standard calculation is represented by the insertion of the Polyakov line with charge two. We thus identify the Polyakov line with the exponential of the dual field

$$ P = \exp \left( \frac{i}{2} \sim \right) $$

and the dual field $\sim$ with the Abelian vector potential

$$ \sim = 2g \; A_0 $$

Up to the monopole induced term, the Lagrangian eq. [21] is equivalent to the sine-Gordon theory of the dual field $\sim$ in eq. [21]. With the identification in eq. [49], this is

$$ \frac{2}{T} (\theta_0 A_0)^2 + \cos \left( \frac{2g}{T} A_0 \right) $$

The monopole induced term also can be written in terms of the vector potential. Its form in terms of the Polyakov line $P$ is precisely the same as the form of the charge plasma induced term in terms of the vortex field $V$. Recall that the origin of the plasma induced term $\cos \sim$ in eq. [21] is the dimensionally reduced Skyrme term $\cos \sim$ of eq. [14]. Thus just like we derived the sine-Gordon Lagrangian eq. [21] starting from the effective Lagrangian for the vortex field, we can follow the same steps backwards but this time expressing everything in terms of $P$. Due to this duality between $V$ and $P$ we conclude that the monopole induced term is the dimensionally reduced Skyrme term for the Polyakov line. The full effective Lagrangian for the vector potential is then

$$ L = \frac{2}{T} (\theta_0 A_0)^2 + \cos \left( \frac{2g}{T} A_0 \right) + \frac{a^2}{4} \ln \sim (\theta_0 \theta_0 \theta_0 \theta_0) $$

20
The monopole in this Lagrangian is represented by a vortex of the field \( \frac{1}{2} A_0 \) with unit vorticity. The coefficient of the Skyrme term in eq. (51) is such that the action of such a unit vortex is equal to the action of the "core" of the monopole.

The cosine term in this expression is the potential for \( A_0 \) induced by the nonvanishing density of the charged particles in the therm al ensemble. Naturally, it contains the Debye "electric" mass term for \( A_0 \) and also higher interactions. Note that as opposed to strongly interacting theories, where similar effective Lagrangians have been derived only in the derivative expansion, the Lagrangian eq. (51) is valid on all distance scales longer than \( 1=\frac{T}{T_{GG}} \).

Thus in principle it can be used to calculate correlation functions in a large momentum range. However, if one is interested in the long distance behavior of the correlators, at temperatures above \( T_{GG} \) the higher derivative Skyrme term can be neglected. This is in accordance with our analysis of the previous section which showed that the monopole induced term is irrelevant above \( T_{GG} \).

An interesting example of a correlation function is the correlator of vortex operators \( \langle V(x)V(y) \rangle \). At low temperatures, since the magnetic \( Z_2 \) symmetry is spontaneously broken this correlation function tends to a constant at large separations. The corrections to this constant value are given by the correlator of the field \( A_0 \). At zero temperature the correlator is

\[
\langle V(x)V(y) \rangle = \frac{g^2}{8} \exp \left( \frac{1}{2} \right) \langle x \rangle \langle y \rangle = \frac{g^2}{8} \exp \left( \frac{16}{g^2} Y_3(x,y) \right) \tag{52}
\]

where \( Y_3(x,y) \) is the 3d Yukawa potential with the mass. At low temperature \( (T < T_{GG}) \) the infrared asymptotics (at distances \( j \langle x \rangle \langle y \rangle > 1=T \) ) is instead

\[
\langle V(x)V(y) \rangle = \frac{g^2}{8} \exp \left( \frac{16}{g^2} \right) \frac{2T}{2} Y_2(x,y) \tag{53}
\]

with \( Y_2(x,y) \) - the 2D Yukawa potential with the mass which includes the effects of integrating out the nonzero Matsubara modes, as calculated in [3]. This expression follows from eq. (27) neglecting the cosine term, which is indeed negligible in the infrared.

At high temperatures \( T > T_{GG} \) instead it is convenient to use eq. (52) with the
omission of the third term [11]. The calculation of the correlator of the vortex operators proceeds along the lines of [13, 14]. The insertion of \( V(x) \) and \( V(y) \) creates the \( Z_2 \) domain wall stretching between the points \( x \) and \( y \). In terms of the sine-Gordon theory eq. (51) this domain wall is just the kink, and thus the domain wall tension is equal to the soliton mass \( M_s \) [14]. The correlator then is

\[
< V(x)V(y) > = \exp f M_s \delta (x-y) 
\]

with the soliton mass reading as

\[
M_s = a \frac{1}{p \Gamma} \left( \frac{p+1}{2} \right)^\frac{1}{p} \frac{(p+1)}{p \Gamma} 2^{-\frac{p+1}{2}} 
\]

where

\[
p = \frac{g^2}{8} \frac{T}{Q} 
\]

Thus we find that the correlation function of the vortex operators decreases exponentially in the high temperature phase as it should in the phase with restored symmetry. Note that were we to neglect the Debye mass term we would have found that below \( T_{BKT} \) the correlator tends to a constant at infinity, while at \( T > T_{BKT} \) it does decay at large distances but only as a power, since the mass of the soliton would vanish.

We note that the result eq. (54) implies that in the deconfining phase the monopoles are connected linearly. We remind the reader that insertion of an operator \( V \) is equivalent to creation of a monopole [12]. Thus the logarithm of the correlation function can be interpreted directly as the intermonopole potential. Indeed at zero temperature one can read off the intermonopole potential from eq. (52). The potential is the Debye screened 3D Coulomb potential. At nonzero temperature eq. (53) gives it as the 2D Coulomb potential at short

---

8Our calculation is only valid in the range of temperatures below the Higgs expectation value \( h \). At \( T > h \) the theory becomes essentially nonabelian, since the Higgs particle as well as \( W \) bosons are present in the vacuum in large numbers, and our methods become inapplicable. In fact in this range there may be another phase transition corresponding to the "melting" of the Higgs expectation value. Our analysis in this and previous sections has nothing to say about this regime.

9Strictly speaking \( V \) creates a \( Z_2 \) monopole - that is the monopole with half the magnetic charge than the "t'Hooft-Polyakov solution. However the interaction between these objects is qualitatively the same.
distances, again screened at distances $x^2 > 1$. At high temperature then we see from eq. (54) that the interaction between the monopoles is linear with the string tension equal to $M_s$. Thus the behaviour of the monopoles is in many senses "dual" to that of electric charge.¹

Finally we wish to comment on the behaviour of the spatial Wilson loop in this model. One expects the spatial Wilson loop to have an area law. This area law has a simple interpretation in terms of the thermal ensemble of magnetic vortices. The vortex picture is generally true and as discussed in [], holds even in theories where the Wilson loop at zero temperature has a perimeter behaviour. We have nothing to add to the discussion of the vortex ensemble picture, since our present approach is not formulated directly in these terms. It is curious to note however, that the spatial string tension can not be calculated at all in the dimensionally reduced theory of the eld, eq. (27), although it can be easily shown that it does not vanish. Consider the calculation of the Abelian Wilson loop $W(C)$. As discussed in [], it is the generator of the magnetic $Z_2$ transformation inside the contour $C$. The path integral representation of this expectation value is

$$< W(C) > = \int d^2 \phi \exp \left( \frac{g^2}{8} \int j(x) \delta(x) \right) \cos 2 \theta$$

with

$$j(x) = \begin{cases} \frac{g^2}{8} \delta(x) \phi(x) & \text{if } x \in S \\ 0 & \text{else} \end{cases}$$

and $S$ is the area bounded by $C$ lying in the $x_0 = 0$ plane. This expression clearly can not be dimensionally reduced, since the external current $j$ has components at all $M$ Matsubara frequencies. If we nevertheless naively disregard the higher $M$ Matsubara modes of the eld, we negate

$$W(C) = e^{\frac{g^2}{8} \pi S}$$

¹ Of course one always has to keep in mind that physically monopoles and charges are very different objects in this model: the charges are particles, while the monopoles are instantons.

¹¹ The contribution of the zero $M$ Matsubara frequency is trivial, since the path integral in this sector is dominated by the configuration $(x) = \frac{g^2}{8} \delta(x) \phi(x)$ which has vanishing action.
Since the cutoff on the reduced theory, $a$ is of order $1/T$, parametrically this result is precisely what we expect / $g^2 T$. However to determine the exact numerical value we would have to look into details of the nonzero Matsubara mode configurations.

6 Conclusions

In this paper we have studied the deconfining phase transition in the 2+1 dimensional Georgi-Glashow model. This model to this day remains the only analytically solvable confining theory, and it is therefore interesting to see how the deconfining transition occurs in this simple yet nontrivial setting.

We found that the phase transition is indeed associated with the restoration of the magnetic $Z_2$ symmetry with the universality class of 2D Ising model. We have shown that the transition is driven by the appearance of the charged plasma rather than by the binding of the monopoles. The presence of the monopoles is significant, since it pushes the value of the critical temperature up by a factor of two (in the infinitely heavy Higgs limit) relative to the plasma transition in the noncompact electrodynamics. We have derived the effective action in the high temperature phase without recourse to the derivative expansion and have calculated the correlation function of the vortex operators. These correlators decay exponentially above the phase transition, which is consistent with the restoration of the magnetic symmetry. This also shows that the monopoles are bound linearly at high temperatures due the charged plasma effects, and these effects are much more important than the monopole self-interaction, which by itself leads only to a logarithmic intern monopole potential.

We believe that these qualitative features are universal and should generalize not only to the strongly interacting non-Abelian theories in 2+1 dimensions, but also in large measure to 3+1 dimensional QCD along the lines discussed in [8]. Unfortunately we are not yet able to generalize the present quantitative analysis to these more interesting theories.
