Abstract

The usual see-saw formula is modified by the presence of two Higgs triplets in left-right symmetric theories. The contribution from the left-handed Higgs triplet to the see-saw formula can dominate over the conventional one when the neutrino Dirac mass matrix is identified with the charged lepton or down quark mass matrix. In this case an analytic calculation of the lepton asymmetry, generated by the decay of the lightest right-handed Majorana neutrino, is possible. For typical parameters, the out-of-equilibrium condition for the decay is automatically fulfilled. The baryon asymmetry has the correct order of magnitude, as long as the lightest mass eigenstate is not much lighter than $10^6$ to $10^8$ eV, depending on the solution of the solar neutrino problem. A sizable signal in neutrinoless double beta decay can be expected, as long as the smallest mass eigenstate is not much lighter than $10^3$ eV and the Dirac mass matrix is identified with the charged lepton mass matrix.
1 Introduction

The impressive evidence for non(vanishing neutrino masses \[1\]) opens the possibility to study a number of new physics problems on a broader phenomenological basis. For the first time non Standard Model physics is seen. For example, the observed baryon asymmetry of the universe cannot be explained by conventional Standard Model physics \[2\]. Since the leptogenesis mechanism proposed by Fukugita and Yanagida \[3\] requires very massive right(handed) neutrinos, it is a fruitful task to try to connect the properties of the known light neutrinos with their heavy right(handed) counterparts. For this, certain assumptions concerning the high(energy) part of the theory have to be made. Several recent articles dealt with this subject \[4,5,6,7,8,9,10,11,12\]. In \[13\] we argued that the left(handed) Higgs triplet \[\Delta\] which was absent in the previous papers \[\Delta\] gives the most important contribution to the neutrino mass matrix (see also Refs. \[14\]). In addition to the triplet contribution there is a correction from the usual see{sym} term \[m_D M^1 R\]. The large top quark mass makes this see{sym} contribution comparable to the triplet contribution if \[m_D\] is identified with the up quark mass matrix. This is no longer the case if the mass scales in \[m_D\] are determined by the charged lepton or down quark masses. The neutrino mass matrix is then described mainly by the Higgs triplet contribution. This has the remarkable consequence that the mixing matrix, which diagonalizes the light left(handed neutrino mass matrix and is measured in oscillation experiments, is identical to the one which diagonalizes the heavy right(handed) mass matrix, which governs the lepton asymmetry. In addition, the masses of the heavy right(handed Majorana neutrinos are proportional to the masses of the light left(handed ones. A part from this aesthetically attractive property, the scenario allows to derive very simple analytical results on the baryon asymmetry in terms of the measured oscillation parameters and the yet unknown phases in the mixing matrix. We end that with natural choice of parameters the observed value of \[\frac{\alpha}{\sqrt{3}}\]

\[
Y_\beta' \approx (0.1 \ldots 1) \times 10^0 ;
\]

is predicted. Within our scenario, it is possible to obtain a limit on the lightest mass eigenstate \[m_1\], which is \[10^{-6} (10^{-7}; 10^{-8})\] eV for the small mixing (large mixing, vacuum) solution of the solar neutrino problem. Furthermore, the out{of}equilibrium condition \[H (M_1)\], where \[H\] is the decay width of the lightest heavy Majorana and \[H (M_1)\] the Hubble constant at the time of the decay, is also fulfilled. Finally, we make the connection to neutrinoless double beta decay and nd that a sizable signal can be expected, as long as the smallest mass eigenstate is not much lighter than \[10^{-3}\] eV and the Dirac mass matrix is identified with the charged lepton mass matrix.

The paper is organized as follows: In Section 2 we summarize how leptogenesis and neutrino oscillations are connected in left(right sym metrical theories. This section summarized the framework described in our earlier paper \[13\]. In Section 3 we perform an estimate of the baryon asymmetry, which explains almost all basic features found in the detailed numerical analysis, presented in Section 4. The interesting connection to neutrinoless double beta decay is drawn in Section 5. Our conclusions are presented in Section 6.
2 Neutrino Oscillation and Leptogenesis in left\{right symmetric theories

The light and heavy neutrino masses are obtained by diagonalizing

\[ \begin{pmatrix} 0 & m_L & m_D^1 \\ m_L^T & m_D & M_R \end{pmatrix} \]

where \( m_L \) (\( M_R \)) is a left\{handed (right\{handed\) Majorana and \( m_D \) a Dirac mass matrix. This yields

\[ m = m_L \quad m_D M_R = \tilde{m} D^T \quad m_D^T. \]

The contribution of \( m_L \) is often neglected, even though it might play an important role in explaining the oscillation data [17]. This matrix is further diagonalized by

\[ U_L^T m U_L = \text{diag}(m_1; m_2; m_3); \]

where \( m \) are the light neutrino masses. The entries of \( U_L \) are then measured in oscillation experiments, see Section 3.1. The symmetric matrix \( M_R \) also appears in the Lagrangian

\[ L_Y = \frac{1}{4} h i \frac{\tilde{m}_{D ij} N_{R j}^0 + \frac{1}{2} N_{R i}^{u T} M_{R ij} N_{R j}^0 + h c}{m_1 \quad m_2 \quad m_3} \]

Diagonalizing \( M_R \) brings us to the physical basis

\[ U_R^T M_R U_R = \text{diag}(M_1^0; M_2^0; M_3^0) \]

and defines the physical states

\[ N_R = U_R^Y N_R^0; \]

In the new basis the Dirac mass matrix appearing in the first part of the Lagrangian Eq. (5) also changes to

\[ m_D = m_D \quad U_R \]

It is the rotated Dirac mass matrix which determines the lepton asymmetry. The asymmetry is caused by the interference of tree level with one-loop corrections for the decays of the lightest Majorana, \( N_1 \!

\[ = \frac{(N_1 ! \quad 1^c)}{(N_1 ! \quad 1^c)} + \frac{(N_1 ! \quad 1^y)}{(N_1 ! \quad 1^y)} = \frac{1}{8} v^2 \frac{1}{m_D} \frac{1}{m_D} 1 \quad \text{Im}(m_D^y m_D^y) \quad (M_2^0 - M_1^0) \]

Here, \( v \) \quad 174 G eV is the weak scale and the function \( f \) includes terms from vertex [3, 14] and self\{energy contributions:

\[ f(x) = \frac{\pi}{x} + \frac{1}{x} (1 + x) \ln \frac{1}{x} \quad \frac{3}{2} \quad x \]

3
The approximation holds for \( x \approx 1 \). To calculate the asymmetry \( \gamma \), we need the Dirac mass matrix \( m_D \) and the matrix \( U_R \) in order to obtain \( m_D \) in Eq. (3). In general, after introducing \( m_D \) in the Lagrangian, one may obtain a very different \( m_D \) after the rotation with \( U_R \).

In our approach, the left- (right-)symmetry \([20]\) plays an important role. It relates the unitary matrices \( U_L \) and \( U_R \) to each other since the triplet induced Majorana mass matrices in Eq. (2) have the same coupling matrix \( f \) in generation space:

\[
m_L = f v_L \quad \text{and} \quad m_R = f v_R ;
\]

(11)

The numbers \( v_{L,R} \) are the vacuum expectation values (vevs) of the left- and right-handed Higgs triplets, whose existence is needed to maintain the left- (right-)symmetry. They receive their vevs at the minimum of the potential, producing at the same time masses for the gauge bosons. In general \([20]\), this results in

\[
v_L v_R \propto M_W^2 ;
\]

(12)

where the constant \( i \) is a model-dependent parameter of \( O(1) \). Inserting this equation as well as Eq. (11) in (3) yields

\[
m = v_L f m_D \frac{f}{M_D} m_D^T ;
\]

(13)

As stated before, the contribution of the left- (right-)handed Higgs triplet to \( m \) is often neglected. However, if one compares the relative magnitude of the two contributions in Eq. (3), denoting the largest mass in the Dirac matrix with \( m \), one finds

\[
\frac{m_D M_R^T m_D}{m_L} = \frac{m^2 m_R}{v_L} M_W^2 , \quad m^2 \propto M_W^2 .
\]

(14)

Here, we only used Eq. (12) and assumed that the matrix elements of \( f \) and \( f^T \) are of the same order of magnitude. It is seen that this ratio is of order one only for the top quark mass, i.e., if one identifies the Dirac mass matrix with the up quark mass matrix. Due to the hierarchical structure of quark masses, the up quark mass matrix can be written as

\[
m_D \propto \text{diag}(0;0; m_t);\]

(15)

where \( m_t \) denotes the top quark mass. This means that only the (33) entry of \( m \) has a contribution from \( m_D M_R^T m_D \). One can then solve for this term and, with the experimental knowledge of \( m \), obtain \( f \). With \( f \) and Eq. (14) we have \( M_R \), whose diagonalization gives \( U_R \), which in turn gives \( m_D \) through Eqs. (11,15). Then, via Eq. (3), one obtains the lepton asymmetry. This program has been performed in \([13]\), finding that from the solutions to the solar neutrino problem only the small angle MSW and vacuum oscillations give an asymmetry consistent with the experimental bound \( [3] \). The large angle MSW
solution gives a very large asymmetry and must be suppressed by tuning the phases in the mixing matrix. The identification of $m_D$ with the up quark mass matrix follows in simple SO(10) models with a 10(plet) of Higgses generating the fermion masses. The mass relation is different in more general situations, when the Higgses belong to the 126 representation. There are also examples where the Dirac masses for neutrinos are zero at tree level and are generated by radiative corrections. In these cases the scale of the Dirac mass is much smaller.

If we now identify $m_D$ with the down quark or charged lepton mass matrix, then the ratio in Eq. (14) is always much smaller than one, so that the second term in Eq. (13) can be neglected and it follows

$$f' \frac{1}{v_L} m :$$

Therefore, with the help of Eqs. (4, 6, 11), one arrives at a very simple connection between the left- and right-handed neutrino sectors:

$$U_R = U_L \text{ and } M_i = m_i \frac{v_R}{v_L}$$

(17)

The striking property is that the light neutrino masses are proportional to the heavy ones. In addition, the left- and right-handed rotation is the same. This is the main result of this work and will be used in the following analysis.

We finally specify the order of magnitude of $v_{LR}$. The maximal size of $v = v_L f$ is $m^2 < 0.1 \, \text{eV}$, which is only compatible with $v_L v_R$ = $M^2$ for $v_L ' = 0.1 \, \text{eV}$ and $v_R ' = 10^{-15} \, \text{GeV}$, as long as $f ' = 0$ or $i = 1$. This means that $v_R$ is close to the grand unification scale and $v_L$ is of order of the neutrino masses, which is expected since $m_L$ is the only contribution to $m$.

3 Estimates

3.1 Neutrino mass matrix

The matrix $U_L$ is measured in neutrino oscillation experiments, a convenient parameterisation is

$$U_L = U_{CKM} \text{ diag}(1; e^i, e^{i(1)})$$

$$= \begin{pmatrix}
0 & C_1 C_3 & s_1 C_3 \\
C_2 & C_1 C_3 & s_1 C_3 \\
s_1 s_2 & s_2 s_3 e^i & C_2 C_3 \\
s_1 C_2 & s_2 s_3 e^i & C_2 C_3
\end{pmatrix} \text{ diag}(1; e^i, e^{i(1)})$$

(18)

In the language of [13] one can say that the work in this paper represents the special case $s = 0$ and $m_t' = m$.
where \( c_i = \cos \theta_i \) and \( s_i = \sin \theta_i \). This matrix connects gauge eigenstates \( ( = e_i \ ; \ ; ) \) with mass eigenstates \( (i = 1;2;3) \), i.e.

\[
= U_{Li} i:
\]

Note that we identify the neutrino mixing matrix in Eq. (13) with the matrix \( U_L \) diagonalizing the neutrino mass matrix Eq. (4). This assumes implicitly that the charged lepton mixing is small.

The CKM "phase" may be probed in oscillation experiments, as long as the large mixing angle solution is the solution to solar oscillations [23]. The other two "major phases" and can be investigated in neutrinoless double beta decay [24,25]. The choice of the parameterization in Eq. (13) reflects this fact since the ee element of the mass matrix \( U_{Le} m_i \) depends only on the phases and . In a hierarchical scheme, to which we will limit ourselves, there is no constraint on the phases from neutrinoless double beta decay [25]. Thus, we can choose these arbitrarily. The mass eigenstates are given as

\[
m_3 = q \frac{m_1^2 + m_2^2}{m_2}, q \frac{m_1^2}{m_1};
m_2 = q \frac{m_1^2 + m_2^2}{m_2}, q \frac{m_1^2}{m_1};
\]

(19)

The values of \( m_2 \) are known to a good precision, corresponding to maximal mixing \( m_2 \). \( m_3 \) is 10 times the values of \( m_2 \), and \( m_2 \) is 10 times the values of \( m_2 \). For the last angle \( \theta_3 \) there exists only a limit of about \( \sin^2 \theta_3 < 0.08 \). See [26] for a recent review of all available data and [27] for a more general discussion of the derivation of neutrino mass matrices.

The results for atmospheric and solar mixing imply two simple forms for \( U_L \), namely

\[
U_L = \begin{pmatrix}
\frac{1}{2} (1 + s_3 e^{i \theta}) & \frac{1}{2} (1 + s_3 e^{i \theta}) & \frac{1}{2} c_2 \\
\frac{1}{2} (1 - s_3 e^{i \theta}) & \frac{1}{2} (1 - s_3 e^{i \theta}) & \frac{1}{2} c_2 \\
\frac{1}{2} c_2 s_3 e^{i \theta} & \frac{1}{2} c_2 s_3 e^{i \theta} & \frac{1}{2} c_2 c_2 C \end{pmatrix} \text{diag}(1; e^{i \delta}; e^{i \delta + \epsilon})
\]

(21)

for LMA as well as QVO and

\[
U_L = \begin{pmatrix}
1 & 0 & s_3 e^{i \theta} \\
0 & 1 & 0 \\
\frac{1}{2} s_3 e^{i \theta} & \frac{1}{2} s_3 e^{i \theta} & \frac{1}{2} c_2 c_2 C \end{pmatrix} \text{diag}(1; e^{i \delta}; e^{i \delta + \epsilon})
\]

(22)
for the SMA case. These forms can be used to estimate the magnitude of the baryon asymmetry within our scenario.

3.2 Out of equilibrium condition

Besides CP and lepton number violation, a necessary condition [28] for leptogenesis to work is the out of equilibrium decay of the heavy Majorana neutrinos, i.e.

\[
K = \frac{1}{H (T = M_1)} = \frac{(m_D^\nu m_D^\nu)_1 M_1}{8 v^2} \frac{M_{Pl}}{1\times 6^2 g M_1^2} \approx 1; \quad (23)
\]

where \( \Gamma_1 \) is the width of the lightest Majorana neutrino and \( H (T = M_1) \) the Hubble constant at the temperature of the decay. The number of massless degrees of freedom at the time of the decay is 3, \( 110 < M_1 \) and \( M_{Pl} \) is the Planck mass. However, values of \( K \) smaller than ten still give sizable lepton asymmetry, even though the asymmetry is reduced by lepton number violating washout processes. This suppression is obtained by integrating the Boltzmann equations and can be parameterized by [29]

\[
\begin{align*}
K & = 0.3 \frac{K}{(\ln K)^{\frac{1}{2}}} \quad \text{for } 10 < K < 10^6, \\
& = 2 \left( \frac{1}{K^2 + 9} \right) \quad \text{for } 0 < K < 10 \\
\end{align*}
\]

(24)

Since also the down quarks and charged leptons display a mass hierarchy, we may write the Dirac mass matrix in analogy to Eq. (15) as

\[
m_D^\nu \sim \text{diag}(0,0,m); \quad (25)
\]

where \( m \) might be the bottom quark or tau lepton mass. Inserting this in Eq. (3) and using the approximate forms for \( U_L \) in Eqs. (2122) yields

\[
(m_D^\nu m_D^\nu)_1 = \frac{1}{6} \begin{pmatrix} 0 & 0 & 0 \\ 0 & (1 + 2s_c) & 0 \\ 0 & 0 & (1 + 2s_c) \end{pmatrix} \quad \text{for } \text{SMA}; \quad (26)
\]

where we took only the leading term in \( s_3 \) and set \( c_3 = 1. \) Using Eq. (17) we replace \( M_1 \) by \( \frac{v_R}{\sqrt{2}} m_1 \) and all other quantities by known constants to arrive at

\[
K \sim 1.5 \frac{10^6 \text{eV}}{m_1} \frac{10^{15} \text{GeV}}{v_R} \frac{1}{2} \frac{8}{s_3^2} \quad \text{for } \text{SMA}; \quad (27)
\]

Thus, for typical parameters, the dilution factor is not too small. We shall assume for the following estimates the value \( s_3^2 \approx 1 \times 10^{-6}. \)
3.3 Lepton and baryon asymmetry

From Eqs. (23) and the approximate forms of $U_L$ we calculate the imaginary parts of $(m^2_{D, m_D})_{ij}$ needed for calculating the lepton asymmetry in Eq. (3). For the 12 element

$$\text{Im} \left( m^2_{D, m_D} \right)_{12} = m^4 \text{Im} \left( U_{L, 1} U_{L, 2} \right)^2$$

$$= \frac{m^4}{16} \left( s_2 + 4 s_3 s c_2 \right)$$

for $\text{LM A, Q VO}$

and for the 13 element

$$\text{Im} \left( m^2_{D, m_D} \right)_{13} = m^4 \text{Im} \left( U_{L, 1} U_{L, 3} \right)^2$$

$$= \frac{m^4}{8} \left( s_2 + 2 s_3 s c_2 \right)$$

for $\text{SM A}$ (28)

with the notation $s_2 = \sin(2\theta)$ and so on. Note that the asymmetry is proportional to $(m^2_{D, m_D})_{11}$ and therefore to $s_3^2$ for the SM A case. This might enhance the lepton asymmetry dramatically. However, as seen from the last two equations, for the SM A case, $\text{Im} \left( m^2_{D, m_D} \right)_{1j}$ is proportional to $s_3^2$, which cancels this potentially dangerous term.

From the lepton asymmetry the baryon asymmetry $Y_B$ is obtained by

$$Y_B = \frac{c}{g};$$

where $c' = 0.55$, denoting the fraction of the lepton asymmetry converted into a baryon asymmetry via sphaleron processes. Using the approximate form of the function $f$ in Eq. (11), the mass eigenstates from Eq. (12) and the fact that $M_i = M_j = m_i = m_j$ one finally obtains for the baryon asymmetry for the $\text{LM A and Q VO case}$

$$Y_B \lesssim 4.1 \frac{m}{\text{GeV}} 2 \frac{m_1}{m_2} \left( s_2 + 4 s_3 s c_2 \right) \frac{m_1}{m_2};$$

and $s_2 = \sin(2\theta)$, and that $Y_B$ vanishes for $= = = 0$, in which CP is conserved, and that it

Thus, for comparable values of the phases and $m^2 A < m^2 A$, the first term dominates $Y_B$. Note that $Y_B$ vanishes for $= = = 0$, in which CP is conserved, and that it
is proportional to the square of the largest mass in the Dirac mass matrix. Therefore, if one would take a charged lepton mass matrix, the results for \( Y_B \) will change roughly by a factor of \( \frac{m_3^2}{m_3} \), with 0.2.

To sum up, identifying the Dirac mass matrix with the down quark or charged lepton mass matrix we obtain the simple relations in Eq. (17) which introduces the lightest left-handed neutrino mass in the answers. In our previous paper [13] the presence of the top quark mass did not permit such a simplification because a different diagonalization for \( U_L \) and \( U_R \) had to be performed. As a consequence, \( M_1 \) was not directly proportional to \( m_1 \) but received contributions from \( m_2, m_3 \) and a term of order \( m_t M_W = v_R \). These contributions are all larger than \( m_1 \) so that basically no dependence on \( m_1 \) was evident.

### 3.4 Limit on smallest mass eigenstate

The approximate form of \( Y_B \) in Eqs. (31, 32) can be used to derive a limit on the smallest mass eigenstate \( m_1 \). In principle, it can be exactly zero, since oscillation experiments only measure the difference of the square of two masses. As mentioned already, in [13] there was practically no dependence on \( m_1 \) whereas here it is decisive since \( Y_B \) is directly proportional to \( m_1 \). To get the highest possible \( Y_B \) we choose the phases such that their contribution is maximized and take the lowest possible \( m_2 \), as listed in Eq. (20). The factor \((1 - 2 s_3 c)^{-1} \) can give for \( s_3 < 0.3 \) give an enhancement of about 2.5 at most so that for \( m = m_b \) we obtain:

\[
Y_B \left( \frac{m_1}{10^6 \text{eV}} \right) \begin{array}{ll}
0.6 & \text{for SM A} \\
1.4 & \text{for LM A} \\
2.1 & \text{for Q VO}
end{array}
\] (33)

Therefore, to obtain an asymmetry within the experimental range, \( m_1 \) should not be much smaller than \( 10^6 \) \((10^7; 10^8) \) eV for the SM A (LM A, Q VO) case.

### 4 Numerical Results

To check the estimates made in the previous section we show in Fig. I the baryon asymmetry for three typical values of the three solar solutions,

\[
m^2 = 5 \times 10^6 \text{eV}^2; \quad \tan^2 \theta_1 = 5 \quad \text{SM A} \\
m^2 = 5 \times 10^7 \text{eV}^2; \quad \tan^2 \theta_1 = 1 \quad \text{LM A}; \quad (34)
\]

\[
m^2 = 10^8 \text{eV}^2; \quad \tan^2 \theta_1 = 1 \quad \text{Q VO}
\]

and \( m_3^2 = 3 \times 10^6 \text{eV}^2 \). \( \theta_2 = -4 \) and choose the phases \( \theta = 5 = 6 \) = . The two parameters of the left(right) symmetry, \( v_R \) and \( v_L \), were taken \( 10^{15} \) GeV and 1, respectively.
For $m_D$ we took a typical down quark mass matrix (see e.g. \[31\])

$$
m_D = \begin{pmatrix}
0 & p m_d m_s & 0 & 1 \\
p m_d m_s & m_s & p m_b m_s & A \\
0 & p m_b m_s & m_b & 0
\end{pmatrix},
$$

(35)

where $m_{d,b}$ are the masses of the $d,s$ and $b$ quark. The lowest mass eigenstate $m_1$ is chosen $10^{-5} (2 \times 10^{6})$ eV for the SMA and LMA (Q VO ) case. We find that there is practically no difference when one takes this matrix or the simple form in Eq. (25), showing the model independence of our scenario.

For the SMA case there are areas, in which $Y_B$ becomes very small and even negative. They are not found by our estimates and can be shown to stem from cancellations of terms proportional to $\sin^2 3$ and $\sin^2 1$. There is no significant dependence on $\sin^2 3$ for the LMA case, as also indicated by the approximate expressions in Eqs. (31,32). Regarding Q VO , one sees that for larger $s_3$ the dilution factor rises from about 0.01 to its maximal value. This explains the rise of $Y_B$ with $s_3^2$ for this solution. With comparable phases, the asymmetry of the LMA and SMA case can be of the same order whereas the one for Q VO needs suppression through $m_1$ due to the very low $m_2$. If one inserts our chosen parameters in the approximate forms for $K$ and $Y_B$ in Eqs. (27,31,32), then one finds for $s_3 = 0$ that

$$
Y_B \approx 0.7 \text{ for SM A}
$$

$$
Y_B \approx 0.1 \text{ for LM A}
$$

$$
Y_B \approx 0.1 \text{ for Q VO}
$$

which is in good agreement with the exact result.

5 Connection to Neutrinoless Double Beta Decay

As mentioned before, only the LMA solution provides the possibility to nd leptonic CP violation in oscillation experiments \[23\]. In addition, in the hierarchical mass scheme only the LMA solution might produce a measurable Majorana mass for the electron neutrino \[32\]. Fortunately, the latest SuperKamiokande data \[33\] seem to indicate that LMA is the preferred solution of the solar neutrino problem. The Majorana mass of the electron neutrino is defined as

$$
\text{hm}_i = \sum_i U_{e_i}^2 m_i
$$

(37)

and due to the complex matrix elements $U_{e_i}$ there is a possibility of cancellation \[25\] of terms in Eq. (37). It is therefore interesting to ask if the parameters that produce a satisfying $Y_B$ also deliver a sizable $\text{hm}_i$. In Fig. 2 we show the results of a random scan of the parameter space with a down quark Dirac mass matrix, taking the following values: $m_2$
between $10^5$ and $10^3\text{ eV}^2$, $\tan^2\theta_1$ between 0.1 and 4 and the three phases between zero and $2\pi$. The atmospheric parameters were fixed as before. We choose for the lowest mass eigenstate $m_1 = 10^5\text{ eV}^2$. Included in the plot is the current limit of $m_1 < 0.35\text{ eV}$ [34] and two future limits, 0.01 and 0.002 eV. From 10000 parameter sets, about 2700 give a baryon asymmetry of the correct magnitude. However, most of the points (about 2000) lie below the lowest achievable $m_1$ limit of 0.002 eV. For higher $m_1$, the fraction of parameter sets giving an acceptable $Y_B$ decreases. Form $m_1 = 10^3\text{ eV}$, only 5% give acceptable $Y_B$ and $m_1$.

If on the other hand we identify the Dirac mass matrix with a charged lepton mass matrix, the asymmetry is reduced. A charged lepton mass matrix is obtained from Eq. (33) by replacing the bottom (charm, down) quark mass with the tau (muon, electron) mass. Then, the asymmetry needs a smaller suppression through the phases and $m_1$ can be bigger, going up to its maximal value of about $\frac{1}{2}\left(\frac{m_{\text{max}}}{m_{\text{max}}}\right)^2 0.016\text{ eV}$. This can be seen in Fig. 3 for $m_1 = 10^3\text{ eV}$. Here, about 35% of the parameter sets give a correct $Y_B$ and 29% an $m_1$ above 0.002 eV. For lower $m_1$, this fraction decreases rapidly because the asymmetry decreases.

The $\text{CKM (phase)}$ does not appear in $m_1$. It appears in the asymmetry but turns out to be not very strongly restricted. The reason is that in our parametrization (18) the phase is often connected with the small quantity $s_3$, which results in a small overall dependence of the asymmetry on this phase. Therefore, one can expect a sizable $m_1$ within our scenario as long as the smallest mass eigenstate $m_1$ is not much lighter than $10^3\text{ eV}$ and the Dirac mass matrix is identified with the charged lepton mass matrix. The possibility of detecting $\text{CP violating effects}$ in oscillation experiments remains open, in the sense that within our scenario the phase can take any value. Finally, we remark that for the scenario in [13] an extreme tuning of the parameter is required to obtain a reasonable $Y_B$. Therefore, no sizable signal in neutrinoless double beta decay can be expected if one identifies the Dirac mass matrix with the up quark mass matrix.

6 Conclusions

In a left-right symmetric theory with a left-handed Higgs triplet the light neutrino mass matrix originates from its vev. If in addition the Dirac mass matrix in the seesaw formula is identified with the down quark or charged lepton mass matrix, then a simple connection between the light left-handed and heavy right-handed neutrino sectors emerges. The outcome of (equilibrium) condition for the decay of the heavy Majorana neutrinos is automatically fulfilled and a baryon asymmetry of the correct order of magnitude is produced. The limit on the smallest mass eigenstate $m_1$ is approximately $10^6 (10^7; 10^8)$ for the SMA (LMA, QVO) cases. Within this scenario a sizable effect in neutrinoless double beta decay is expected, as long as $m_1$ is not lighter than $10^3\text{ eV}$ and the Dirac mass matrix is the charged lepton mass matrix. The possibility of finding $\text{CP violation}$ in oscillation experiments remains open.

Figure 1: Behavior of the baryon asymmetry as a function of $\sin^2 \theta_3$ for the parameters as given in Sec. 4. For this plot, the Dirac mass matrix is a down quark mass matrix.

Figure 2: The effective electron neutrino mass $m_\nu$ as a function of $\sin^2 \theta_3$ for $m_1 = 10^{-5}$ eV. 10000 random points were generated, about 2700 give $Y_B$ within 0.1 and 1 and less than 800 an effective mass $m_\nu$ above 0.002 eV. For this plot, the Dirac mass matrix is a down quark mass matrix.
Figure 3: The effective electron neutrino mass $m_\nu$ as a function of $\sin^2 \theta_3$ for $m_1 = 10^{-3}$ eV. 7000 random points were generated, about 2500 give $Y_2$ within 0.1 and 1 and about 2100 an effective mass $m_\nu$ above 0.002 eV. For this plot, the Dirac mass matrix is a charged lepton mass matrix.
