I. INTRODUCTION

A lthough physics in more than t he traditional four dim ensions has b een surm ised to b e im portant for d escribing pheno mena at energies above t he electroweak scale, t he idea is pres ently enjoying ad ditional scrutiny because of t wo m ore recent d evelopm ents.

F irst came t he understand ing of t he strong-coupl ing limit of string t heory in t erms of 11-dim ensional supergravity interacting on spaces with boundaries [4]. Tog ether with t he real ization that observable p articl es can be trapped on these boundaries, or on D-branes, this understanding freed t he string scale from t he Planck mass, allowing it to be as low as the weak scale [5] or at intermediate or grand-unified scales [6]. Such low string scales allow extra dim ensions to be com paratively large, and so (potentially) t o have much richer p heno mena at experimentally accessible energies.

Se cond came t he observation t h at even very small e xtra-dim ensions m ight al so have interesting low-energy im plications if t heir ge om etries are 'warped' [1]. In t his fram ework, t he four-dim ensional met ric has a nontrivial dependence on position in t he extra dim ensions, allowing four-dim ensional properties like masses and couplings to depend in an interesting way on an observer's position with int he extra dim ensions.

A lthough not required by either approach, t he broader class of geometries which are allowed once observable particles are con ned to a brane includes m any con gurations which violate Lorentz invariance within t he observable four-dim ensions by picking out a preferred fram e [7] such as by having graviat ing objects displaced from our brane in t he extra dim ensions. For exam ple, i n t he warped fram e work one can ha ve a 5D line el em ent of t he form

\[ ds^2 = (-\gamma + \gamma_0)dt^2 + dx^2 + \frac{dr^2}{r^2} \quad (1) \]

where t, x are 4-dim entional time and space, r is the extra-dim ens ion, \((r = r^2 = \mathbb{E})\) and \((r = r^2 + Q^2 = r^4)\). I f \(Q = 0\) this is anti de Sitter space with curvature radius L, and there is no Lorentz violation. B ut if \(Q \neq 0\), it is the AdS-Reissner-Nordstrom metric with a singularity at \(r = 0\) and a speed of light which varies with \(r\) as \(c^2(r) = 1 + \ldots\). T he case \(Q = 0\) is important in an extra -di m ensional graviton, the case \(Q \neq 0\) is interesting in an extra-dim ensional graviton, and both may be relevant in the context of extra-dim ensions with Lorentz violation.

Very strong limit s exist on the size of various Lorentz-violating e cts involving ordinary particles [3], so one expe cts these to provide t he most stringent tests of any Lorentz-violating e cts predicted in t he brane-world scen ario. A lthough t his expectation is borne out, t he sur prise in t hese scen arios is always t he com parative di -

culty of finding good constraints in the event that the only known particle living in t he bulk is the graviton, since so little is directly known about t he graviton's prop erties. Som e e cts are par-
in this way [15], strongly restricting the case where the graviton velocity, \(c_g\), is smaller than that of the proton, \(c_p\).

Our purpose in this paper is to provide a com plementary constraint for the case where protons cannot radiate gravitons, and so the above bound does not apply. We obtain our constraint by com puting some of the Lorentz-violating e ects which are in played for ferm ions and photons by radiative corrections involving gravitons. Because the bounds on such corrections for electrons and photons are extrem ely good, we are able to infer reasonably strong bounds on Lorentz violation in the graviton sector.

We end two kinds of e ects, each of which depends on physics at di erent scales. We nd the one-loop graviton-induced contributions to particle phase velocities to be highly suppressed by the mass of the particle involved. This sensitivity is stronger the higher the number of di m ensions the graviton sees. The photon and electron are particularly insensitive to this kind of correction. Because they are so mass-dependent, the largest contributions to light particles are often due to higher-loop graphs within which a one-loop graviton-induced modification to the propagation of a heavy particle (like a W boson or top quark) is inserted. This makes predictions sensitive to the ultraviolet structure of the theory.

Graviton loops also change light-particle dispersion relations by introducing contributions which involve higher powers of the particle momentum. We compute these and nd that they can be generically less ultraviolet sensitive than are changes to particle phase velocities. Interestingly, the low-energy contributions of this form (i.e. the contributions due to the massless 4D graviton) are already large enough to provide interesting bounds.

We organize our presentation as follows. In the next section we discuss in general terms how Lorentz-violating e ects enter into the low-energy 4D theory at energies well below the com pactification scale. This is the regime of interest for experi ments, and is not the regime in which one can consider bulk particles to be moving on ballistic trajectories through the extra di m ensions. Then in section III we discuss the sfermion and photon self energies in general, to identify which features are required in order to make com parison with experimental e ects. Section IV follows with the calculation of the graviton loop, and the derivation of the induced Lorentz violation am ong visible brane-based particles. Given the mass dependence of the results of Section IV, Section V gives conservative estim ates as to the size which might be expected for protons, electrons and protons. Section VI describes the bounds on Lorentz violation for these particles, and com putes the bound which may be inferred indirectly on the strength of Lorentz violation in the gravity sector. Our conclusions are summarized in section VII, and some of the cum issues are presented in appendices.

II. THE 4D EFFECTIVE PICTURE

In the brane-world picture photons and electrons usually are constrained to move on our four-dimensional brane, while gravitons are free to explore the higher-dimensional bulk surrounding space. It is intuitive in this kind of picture that brane and bulk particles might propagate e eectively, since bulk particles might be free to take 'shortcuts' through the extra di m ensions which are forbidden to brane-bound particles [13]. This possibility has been proposed to be, in some instances, a virtue in that it may provide a new way to address some cosmic problems [14-16].

A lthough this kind of ballistic picture is appealingly intuitive, it is not really appropriate for the low energies at which tests of the dispersion relation actually take place. Experiment tests only involve one graviton which we see in 4 di m ensions, and so only involve the very lowest Kaluza-Klein (K K) state. By contrast, assigning the graviton localized trajectories in the extra di m ensions presupposes a localized wave packet in these di m ensions, which cannot be constructed purely from the lowest-energy mode.

We brie y detour in this section to describe how extra-dim ensional Lorentz-violation appears in the low-energy e eective Lagrangian which describes the lowest KK mode. Although we start by using the simplest example of a scalar eld, the conclusions we draw will be shown to be equally valid for higher spin elds.

A. A Scalar Field

Consider, therefore, a bulk scalar eld, \(\phi(x,y)\), where \(x\) labels the 4 di m ensions parallel to the brane, and \(y^n\) labels the n various transverse di m ensions. The four-di m ensional eld content is obtained by resolving into a basis of modes in the extra di m ensions:

\[
\phi(x,y) = \sum_k \phi_k(x) \Phi_k(y) \]

where the basis functions, \(\phi_k(y)\), are eigenfunctions of the appropriate kinetic/mass operator: \(\phi_k = \gamma_k \phi_k\).

The kinetic 4D action for the KK modes, \(\phi_k(x)\), is obtained by inserting the mode expansion into the higher-di m ensional action and integrating the result over the extra di m ensions. Using an assumed form for the extra-dim ensional background metric:

\[
G_{MN} = g_{\phi}(x,y) \Gamma_{MN}(y) \]

one finds in this way:

\[
S = \int \frac{1}{2} \left[ \begin{array}{c} d^4x d^n y \phi G_{MN} \Gamma_{MN} \Psi_M \Psi_N \\ d^4x \phi G_{\phi k \phi k} \phi_k \phi_k \phi_1 + \end{array} \right]
\]
where $G = \det G_{MN}$, etc., and the effective four-dimensional metric governing the kinetic terms is

$$P \frac{G_{kk}}{G_{kk}} (x) + Z d^4 y \frac{P}{ghg} (x,y) u_k(y) u_l(y);$$

(5)

The main point is that the metrics (plural since there is a different metric for each choice of the indices $k,l$) defined by eq. (5), differ, in general, from the induced metric on the brane, which appears in the kinetic term for fields which are trapped on a brane. For instance, for a brane defined by the surface $y = y_0$ the induced metric is simply $g = g(x; y_0)$. This is ultimate the source of Lorentz-violating effects due to the bulk metric.

If we focus purely on the massless four-dimensional modes, which we label by $k = 0$, then we must integrate out the other, more massive, KK modes. The kinetic term for the massless $k = 0$ mode, which we label by $k = 0$, contains the metric $G = G_{00}$ which may differ from the induced metric on the brane. In the rest of this paper we will focus on the implications of this difference.

Two limits of the metric $G$ bear highlighting. First, in the absence of warping of the bulk metric (i.e., if $g(x)$ is independent of $y$) eq. (5) becomes:

$$P \frac{G_{kk}}{G_{kk}} (x) = \frac{P}{ghg} (x) d^4 y \frac{P}{h u_k u_l},$$

(6)

where the second line uses the orthogonality condition of the basis modes, $u_k(y)$. In this case bulk and brane modes see the same metric, for branes defined by surfaces $y = y_0$.

Second, in the absence of a preferred frame in the bulk metric (such as the $A{\bar{D}}S$ metric used by Randall and Sundrum) the metrics $G$ and $M$ must be conformal to one another (i.e., $G = f(x)$ (x)), since Lorentz invariance implies that they must both locally be proportional to the Minkowski space metric.

B. The 4D Graviton

A similar story gives the invariance of Lorentz-violating effects on the propagation of low-energy gravitons within the effective theory below the compactification scale (or the $A{\bar{D}}S$ curvature scale, in the case of RS-II-like models without compactification), although the details are a bit more complicated due to gauge invariance. Our purpose here is to identify the leading contributions of Lorentz violations in the higher-energy theory to graviton propagation in the low-energy 4D theory, and to show that they always may be cast in terms of an appropriate shift of the background metric.

We assume: (i) our interest is in energies very low compared to the compactification scale, allowing a treatment in terms of the low-energy $4D$ effective theory; (ii) there is only a single massless spin-2 graviton mode in this effective theory, and (iii) that the dominant effect of the higher-dimensional theory is to break Lorentz invariance but not translation invariance or rotational invariance (in the preferred frame). Under these circumstances the $4D$ effective theory involves an effective $4D$ metric $\hat{g}$ coupled to an order parameter, $u$, which defines the preferred frame. The assumptions of unbroken rotational invariance imply $u$ is real, and we rescale it so that it is normalized, satisfying $\hat{g} uu = 1$.

On grounds of general covariance, the $4D$ effective theory with the fewest derivatives has the form:

$$L = \frac{1}{2} P \frac{h}{ghg} R + a R u u + \cdots;$$

(7)

for some dimensionless constant $a$. Here the ellipses indicate higher-derivative terms, and we have not written a cosmological constant term, which we assume $a$ to be negligible. (We shed no light in this paper on the vexing cosmological constant problem.) Here $h = 8 G_4 = 1M^2_4$, where $G_4$ and $M_4$ are the usual $4D$ Newton's constant and (rationalized) Planck mass, $M_4 = 2 \times 10^{13} \text{ GeV}$. In order of magnitude we expect $a = 2 \times 2$, where $\hat{g}$ is the scale associated with the Lorentz-violating effects at higher energies. Clearly $a$ is naturally very small to the extent that it is much smaller than the $4D$ Planck scale.

Then our point now follows. The second term of eq. (7) may be completely absorbed by performing the following field redefinition:

$$g ! g \frac{a}{2} \hat{g} + 2 uu;$$

(8)

After having performed this redefinition (and a constant rescaling of the metric), graviton fluctuations about the space are described in terms of the expansion $g(x) = G + 2 \frac{a}{2} \hat{g}(x)$, in eq. (8), using

$$G = \frac{a}{2} uu;$$

(9)

where $\hat{g} = \text{diag}(1; 1; 1)$ is the usual Minkowski space metric, $u = u$, and $\frac{a}{2}$ is a small quantity which we shall see has the interpretation as a change in the maximum propagation speed, $c_L$, of the graviton. The field

$$u ! u,$$

(10)

and we follow W einberg's curvature conventions.

M cm enters 4-vectors are upper case (P), the spatial vector is boldface (p), the magnitude of the spatial piece is lower-case (p).
hence the canonically-normalized field describing graviton propagation.

Just as was the case for the scalar field, the leading effect of higher-energy Lorentz violation is in this way seen to be a modification of the background metric through which the graviton propagates.

As a concrete illustration of this general argument, we can compute the effective 4D gravitational metric corresponding to eq. (3), treating the Lorentz-violating term as a perturbation. The 4D effective gravitational action can be obtained by expanding the 5D action $S$ to linear order in $g = (\frac{r^2}{r_1^2}) = r_1$, treating the graviton propagating field as a perturbation. The 4D effective action is given by $S = -\frac{1}{2}M_5^3 \int \frac{r}{r_1} \frac{r_2}{r_1} \left\{ \frac{\partial^2}{\partial r \partial r} - \frac{4}{r^2} + \frac{\partial^2}{\partial r \partial r} \right\} dx dy + \frac{1}{r_1^2} \left( \frac{\partial^2}{\partial x \partial r} + \frac{\partial^2}{\partial y \partial r} \right) \right\} \right\} \right\}$ (10)

The correction in $g_{rr}$ can be neglected to leading order in $r$. Then

$$S = \frac{1}{2}M_5^3 \int \frac{r}{r_1} \frac{r_2}{r_1} \left\{ \frac{\partial^2}{\partial r \partial r} - \frac{4}{r^2} + \frac{\partial^2}{\partial r \partial r} \right\} dx dy + \frac{1}{r_1^2} \left( \frac{\partial^2}{\partial x \partial r} + \frac{\partial^2}{\partial y \partial r} \right) \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \right\} \r
of general relativity we imagine $< 10^{-6}$.

A. Photon Propagation

We identify in this section those parts of the graviton-induced vacuum polarization which have in plications for the dispersion relation of transversely-polarized photons. We first write the most general form for the vacuum polarization which can be built from the tensors,

$$ G = (1 - \frac{i}{\gamma} u \cdot u) \text{and} \text{the constant 4-vector,} \quad P, \text{which is consistent with symmetry} \quad (\mathbf{P} = 0) \text{and transversality} \quad (\mathbf{P} \cdot \mathbf{P} = 0). \text{The most general form is:}$$

$$ = A \frac{P \cdot P}{P^2} + B \mathbf{u} \cdot \mathbf{u}$$

where at this point A and B are arbitrary functions of the two independent variables, $P^2$ and $P \cdot u$.

The dispersion relation is found by searching for the zero eigenvalues of the inverse propagator, $\epsilon_0 = 0 +$ where $\epsilon_0 = (P^2, P \cdot P)$. In particular, our interest is only in those which are transverse (orthogonal to the pure gauge directions). Working in the rest frame $e$, $u = (1; 0; 0; 0)$, and taking the photon momentum to point in the $z$-direction (i.e., $P = (0; 0; 0; p)$), the top requirement is $0 = 0$ in the directions $; x; y$.

A simple calculation using eq. (13) shows that this implies:

$$!^2 p^2 + A (!; p) = 0;$$

(14)

Since A is perturbatively small, it suffices to write the dispersion relation as $! = \epsilon_0 + !_1$, where $\epsilon_0 = p$, and to evaluate A with $! = !_0$. This leads to the present section's main result:

$$!_1 = \frac{1}{2!_0^2} A (!_0; p);$$

(15)

As we shall now, we admit an expansion at low energies in powers of $P^2$ and $P \cdot u$, leading to the form

$$A (!_0; p) = p^2 + p^4 + \cdots;$$

(16)

where rotational invariance precludes the appearance of odd powers of $p$. Using this in eq. (15) and comparing the result with the general 4D photon dispersion relation

$$!^2 (p) = p^2 c^2 + b \quad p^4 + O (p^6);$$

(17)

we readily identify

$$c^2 = 1; \quad b = :$$

(18)

B. Fermion Propagation

We next ask how loop contributions to fermion selfenergies can modify fermion dispersion relations. We work within the rest frame defined by $u$. Writing the inverse electron propagator as $S = S_0 + \ldots$, with $S_0 = (\mathbf{E} + m_0)$, we see that to leading order in perturbation theory the zeroes of $S$ satisfy $P = (E; p)$, where $E = E_0 + E_1$ with $E_0 = p^2 + m_0^2$ and:

$$1 \not{=} E_1 = (E_0; p);$$

(19)

For small $p$, has the expansion

$$(E_0; p) = A + B (i \not{=} p) + C p$$

$$\not{=} D \not{=} p + E p$$

(20)

and so eq. (13) inplies a dispersion relation of the form

$$E^2 = m_0^2 + p^2 c_0^2 + b_0 p^4 + \cdots;$$

(21)

with

$$m_0 = m_0 \quad A +$$

$$c_0^2 = 1 \quad 2 (B + m_0 C) +$$

$$b_0 = 2 (D + m_0 E) +$$

(22)

(23)

(24)

In these last three equations the subscript f denotes the fermion species, and the ellipses indicate higher-order contributions.

Since it is the quantities $c_0^2$ and $b_0$ which we wish to compare with experiments, the implications of graviton loops may be obtained by computing the coefficients $B$ through $E$.

IV. LOOPS: GRAVITON CALCULATIONS

In this section we compute the one-loop self-energy which is obtained when a fermion or photon emits and reabsorbs a virtual graviton, as in gs. 1 and 2. We present our results in three steps. First, since the integrals involved strongly diverge in the ultraviolet, we make some general remarks about the correct way to treat these divergences before describing the calculations themselves.
We then evaluate the graviton loop in two steps, motivated by the picture that Lorentz violation arises from extra dimensional graviton. These loops have the virtue of only involving known particles and couplings, and so the results we obtain are com paratively robust. They describe the graviton contributions within the effective 4D theory, well below the compactification scale, $M_c = 1/r$, where $r$ is a measure of the linear size of the extra dimensions. In the case of a single noncompact extra dimension, the effective theory is good below the bulk curvature scale $\frac{\sqrt{5}}{	ext{5 Plank mass}}$, where $\sqrt{5}$ is the bulk cosmological constant and $M_5$ is the 5-D gravity scale.

Next, we compute the contributions of gravitons in the effective theory between $M_c$ and the scale $M > M_c$ associated with the extra-dimen sional Lorentz violating physics. Since the theory is extra-dimensional in this energy range, this involves calculating the loop contributions of higher KK graviton modes. In order to do this, we make several simplifying assumptions about the nature of the extra-dimen sional Lorentz violation, which we believe succeed for the purposes of establishing the order of magnitude of the extra-dimen sional result.

### A. Ultraviolet Divergences

In d spacetime dimensions the gravitational coupling has dimension $d^2 M_d^{1-d/2}$, where $M_d$ is the d-dimensional Planck mass. On d dimensional grounds we therefore expect the most divergent contribution to one-loop brane-particle dispersion relations to be

$$c^2 \frac{1}{d^2} M^2 + b^2 \frac{1}{d^4} M^4; \quad (25)$$

where $b$ is the ultraviolet cut-off scale.

As usual within an effective theory, this indicates that the result is most sensitive to the most energetic degrees of freedom in the problem, suggesting that calculations within the full theory would produce results that are of order $c^2 \frac{1}{d^2} M^2$ and $b^2 \frac{1}{d^4} M^4$, where $M$ might be the mass of a heavy particle which was integrated out to produce the low-energy effective theory.

As we shall see, the above mass-dependence is roughly right, although some care is required due to the appearance of power-law divergences [23]. Care is required because, although the renormalization group ensures that the coe cient of large logarithms like $\log(M)$ in observables quantities like $c^2$ or $b$ may be read off from the coe cients of log divergences (like $\log(1)$) within the effective theory, the same e is not true for higher (power-law) divergences. As a result in this section we ignore all power divergences, and compute only the log-divergent parts of the results. If the results do not have log divergences (as will be the case with an odd number of extra dimensions), then we compute only the finite parts of the loops.

Neglecting the power divergences minimizes the Lorentz symmetry violation which is seen by particles on the brane, and so leads to conservative conclusions. It corresponds to considering the theory in which brane-bound particles respect Lorentz invariance at the energy scale where the theory becomes 4D dimensional. We return in Section V to the issue of contributions which are proportional to positive powers of large mass scales, $M$, by considering higher loops which explicitly involve more massive virtual particles. We shall therefore see that naive power-counting estimates do correctly reproduce the $M$ dependence of the results, but $M$ is in important dimensionless loop factors.

In practice the finite and log-divergent terms are most easily obtained within the dimensional regularization, with which power-law divergences do not arise. We have computed our results both using dimensional regularization and using an explicit ultraviolet cutoff, however, and have verified that the answers obtained are the same in both cases.

### B. Four-dimensional Graviton

The Feynman rules for fermions and gravitons in the absence of Lorentz-violating effects are standard, and are obtained by linearizing the Dirac-Einstein-Hilbert action in curved space,

$$L = \mathcal{P}^{-1} \left( \frac{1}{2} R + \mathcal{Q}(\mathcal{Q} + m) + \frac{1}{4} \mathcal{F}^2 \mathcal{F} \right); \quad (26)$$

about at space: $g = 1 + 2 \vartheta h$. As before $\vartheta$ denotes the rationalized Planck mass in 4D: $M_4 \simeq 10^{18}$ GeV, $h$ represents the canonically-normalized graviton field. A recent statement of the resulting Feynman rules can be found in references [2] [22].

As we have argued in previous sections, we know that the only Lorentz-violating modification to these rules consists in replacing the Minkowski metric, $\mathcal{G}$, with the nonstandard metric, $\mathcal{G}$, when linearizing the first term in eq. (24) to obtain the graviton propagator. In deD obedience this gives:

$$G = \frac{\mathcal{P}}{\mathcal{G} \mathcal{Q} \mathcal{Q}} q^2; \quad (27)$$

where

$$\mathcal{P} = \frac{1}{2} \left( \mathcal{G} \mathcal{G} + \mathcal{G} \mathcal{G} \mathcal{G} \mathcal{G} \mathcal{G} \right); \quad (28)$$

and $* \neq *$ not to be confused with $\mathcal{G}$ is the infinitesimal which ensures the propagator satisfies Feynman boundary conditions. The fermion propagators and
vertices arise on the brane, and so use only the usual Minkowski metric.

1. The Photon Vacuum Polarization

After Wick rotation, the one-loop Feynman graph in which a virtual graviton is emitted and reabsorbed by the photon (Fig. 1) leads to the following expression for the photon vacuum polarization:

$$\frac{2}{2} \frac{Z d^4 Q}{(2 \pi)^2} \frac{N}{D}; \quad (29)$$

where $D = (P \cdot Q) G - Q \cdot Q$ and

$$N = V \cdot (P \cdot P \cdot Q) V \cdot (P \cdot Q \cdot P) P; \quad (30)$$

Appendix A gives explicit expressions for the vertex functions, $V \cdot (P \cdot Q)$. In these expressions, all dependence on the metric $G$ is explicit, and the brane metric, $\gamma$, is to be used to perform any implicit index contractions, such as in $(P \cdot Q)$. Evaluating this expression (we used the programs FORM and MATHEMATICA to perform the tensor contractions), Taylor expanding in powers of $= q \cdot 1$ and performing the momentum integral gives the following expression for the coefficient function, $A$, of eq. (13):

$$A (\gamma, p) = \frac{304}{15} 4^2 p^4 + O (3); \quad (31)$$

where $4 = (4 = 8)^2 L$. Here $L = \log (\frac{2}{2} = 2) = 2 = (4 = n)$, where the last equality is evaluated using an ultraviolet cutoff $\gamma, \gamma$, and the second regularizes by continuing the spacetime dimension $n$, away from 4. $\gamma$ is an arbitrary scale. We ignore the finite part of the integral relative to its log-divergent part.

Compared with the general expressions provided earlier, gives the following dispersion coefficient:

$$c^2 = 1 = 0; \quad b = \frac{304}{15} 4^2; \quad (32)$$

2. The Fermion Self-Energy

We proceed in a similar way for the changes to the fermion self energy. Evaluating the one-loop Feynman graph using the graviton propagator of eq. (27), and Wick-rotating to Euclidean momenta, leads to the following expression for the fermion self energy:

$$4 = \frac{2}{2} \frac{Z d^4 Q}{(2 \pi)^2} \frac{N_1}{D}; \quad (33)$$

where

$$N_1 = \frac{1}{2} G \left\{ i\gamma_5 Q + m \right\} - \frac{1}{2} G \left( 2P \cdot Q \right) \left( 2P \cdot Q \right); \quad (34)$$

A gain, all dependence on the metric $G$ is explicit, and the brane metric, $\gamma$, is used to perform the implicit index contractions in $(P \cdot Q) \gamma$. To derive this we used the simple vertex function $(k_1 + k_2) + (k_1 + k_2)$ of ref. [24] for the fermion-fermion-graviton coupling rather than the one com plicated one of [22], which includes an extra term $(k_1 + k_2 + 2m)$. The neglect of this extra term is justified even within loop graphs because it vanishes if the fermion field equations are used. This ensures that it is an irrelevant operator, in the sense that it can be removed by performing a field redefinition of the fermion field $\gamma$.

We have evaluated this integral to the lowest two orders in the small parameter $\gamma = q \cdot 1$, using the programs FORM/MATHEMATICA to keep track of the various $4$-vectors in the problem. We end the following results for the logarithmically divergent part of the coefficient $A$ through $E$ of eq. (20):

$$\begin{align*}
A_4 &= m^3 4^4 + 13 + \frac{33}{2} 2^2 + \cdots; \\
B_4 &= m^2 4^4 + 10^2 + \cdots; \\
C_4 &= \frac{m^4}{3} 4^4 + 35^2 + \cdots; \\
D_4 &= 4^6 + \cdots; \\
E_4 &= 0 + \cdots.
\end{align*} \quad (35)$$

where as before $4 = (4 = 8)^2 L$, with $L = \log (\frac{2}{2} = 2) = 2 = (4 = n)$.

These imply the following contributions to the dispersion relation of eq. (24):

$$\begin{align*}
A_4 &= m^3 4^4 + 13 + \frac{33}{2} 2^2 + \cdots; \\
B_4 &= m^2 4^4 + 10^2 + \cdots; \\
C_4 &= \frac{m^4}{3} 4^4 + 35^2 + \cdots; \\
D_4 &= 4^6 + \cdots; \\
E_4 &= 0 + \cdots.
\end{align*} \quad (35)$$
For the case of interest, $\alpha > 0$, we see that $c_2^2 < 1$ corresponding to fermions propagating slower than light. It follows that (for a given momentum $p$) the fermion energy is depressed compared to the photon energy for small $p$.

Notice that the coefficients $b_1$ and $b_2$ both arise at $O(\gamma^2)$, and so their sign (which is negative for both) does not depend on the sign of $\gamma$. Furthermore, these terms satisfy $b_1 > b_2$. These terms therefore act to raise the fermion energy relative to the photon, and so act in the opposite direction of the effect of $c_2 < c$ (when $\alpha > 0$).

### C. Higher-dimensional Gravitons

We may now estimate the contributions of the higher KK graviton modes to the propagation of brane-based fermions. Rather than doing so by performing a sum over a tower of 4-D KK states, we proceed by directly performing the loop graph using higher-dimensional gravitons.

The first step is to specify what the higher-dimensional metric is about which the graviton quantum is to be considered. In principle this should be the metric which describes the gravitational field of the object or objects in the bulk, whose presence gives rise to the preferred frame in which violations of Lorentz invariance. Since the explicit form for such metrics is rarely known, we proceed by a more approximate route.

Our approximation is based on the observation that higher-dimensional graviton loops are ultraviolet sensitive, with their dominant contributions arising from the circulation of very short-wavelength modes. So long as the wavelength of these modes is much shorter than the radius of curvature of the background Lorentz-violating metric, it should be sufficient to replace the background metric by one which is approximately flat, but Lorentz-violating. In particular, this should be sufficiently accurate for our purposes of estimating the order-of-magnitude of the resulting loop-generated contributions to fermion propagation on the brane.

Accordingly we imagine the higher-dimensional graviton to propagate about a metric in which there is a preferred frame $\mathcal{F}$ defined by an approximately constant $D$-vector, $\mathbf{u}$. Such a metric is again described by eq. (33), although with $G$ now being $d$-dimensional.

Linearizing the extra-dimensional Einstein-Hilbert action about this metric ($\mathcal{G}_{ab} = G_{ab} + 2 \frac{\alpha}{d} G_{ab}$, we nd the following $d$-dimensional graviton propagator in de Donder gauge:

$$G_{ab} = \frac{\delta^2}{\partial^2_x} (G_{ab} + G_{ac} G_{cb}) \frac{1}{\delta^2} G_{ab}$$

(37)

Again, in this expression is the in which enforces Feynman boundary conditions. The quantity $\alpha$ is related to the $d$-dimensional Newton's constant and Planck mass by $\alpha = 8 G_{d} = (1 - \alpha^2) \frac{d}{d}$. We take the fermion and photon to move on a 3-brane, for which the induced metric is the usual $M$inkowski metric.

#### 1. The Photon Vacuum Polarization

Computing the photon vacuum polarization with this propagator gives no correction to the photon dispersion relation at low energies, if the number of dimensions exceeds the usual four. This can be understood purely in terms of dimensional analysis, and the fact that we are computing only the finite or log-divergent contributions. The one-loop contributions to the photon self-energy have two graviton vertices, so they are proportional to $\alpha^2$. Since the log-divergent and finite parts do not involve powers of the cut-off, the only quantity which can be used to make a dimensionally correct answer is the photon momentum $p$. Thus the result is proportional to $\alpha^2$. This gives a $p_4$ correction to the dispersion relation, but only if $d = 4$. For $d > 4$, it always gives only a higher than quartic power of $p$. (Section V discusses the physics of the power-divergent contributions to $c_2^2$).

#### 2. The Fermion Self-Energy

Evaluating the one-loop fermion self-energy graph using the $d$-dimensional graviton propagator of eq. (38), and $\varphi$-x-rotating to Euclidean momentum, leads to the following expression for the fermion self-energy:

$$\alpha = \frac{d}{2} \left[ 2 \frac{\alpha}{d} \frac{d^2 Q}{(2\gamma)^2} \frac{N_1 + N_2}{D} \right]$$

(38)

where $N_1$ is as given by eq. (34) and

$$N_2 = C_d \left( 2P \frac{Q}{(2\gamma)^2} \frac{P + Q}{(2\gamma)} \frac{Q}{(2\gamma)} \right)$$

with $C_d = (d - 4) = 16(d - 2)$.

Evaluating the integral in powers of $\gamma$ gives an ultraviolet divergent result. We have evaluated the result using both dimensional regularization and an explicit cut-off, and have veri ed that the coefficients of the logarithmally-divergent and pole terms are the same in both cases. For odd dimensions the integrals are finite in
Since dimensional regularization, and we have verified that the result agrees with the finite part when evaluated with an ultraviolet cut-off.

We are led in this way to the following expressions for the quantity $c_2^\gamma$ for dimensions $d = 5$ through $10$. (We give the quantities $A$ through $E$ in Appendix B):

$$c_2^\gamma = m_2^{d-5} \frac{110}{9} + \frac{239}{9} \gamma^2 + \cdots; \quad (d = 5)$$

$$= m_2^{d-6} \frac{48}{9} + \frac{99}{5} \gamma^2 + \cdots; \quad (d = 6)$$

$$= m_2^{d-7} \frac{616}{75} + \frac{244}{15} \gamma^2 + \cdots; \quad (d = 7)$$

$$= m_2^{d-8} \frac{464}{63} + \frac{890}{63} \gamma^2 + \cdots; \quad (d = 8)$$

$$= m_2^{d-9} \frac{333}{49} + \frac{1245}{98} \gamma^2 + \cdots; \quad (d = 9)$$

$$= m_2^{d-10} \frac{115}{18} + \frac{421}{36} \gamma^2 + \cdots; \quad (d = 10); \quad (40)$$

Here the quantities $m_2^d$ are defined in terms of the couplings $\alpha$ by:

$$5 = \frac{5}{2} \alpha^2; \quad 6 = \frac{2}{3} \alpha^2 \log(2); \quad 7 = \frac{\gamma}{3 \alpha^2}; \quad 8 = \frac{2}{3} \alpha^2 \log(2); \quad 9 = \frac{2}{15 \alpha^2}; \quad 10 = \frac{4}{3 \alpha^2}. \quad (41)$$

As before $L = \log(\frac{2\alpha}{\gamma})$ when a cut-off is used, or $L = 2\alpha(d-n)$ in dimensional continuation of $n$ away from $n = d$.

Notice that the corrections to $c_2^\gamma$ which are implied in this way are not universal in size for all fermion masses, being suppressed by powers of $\alpha$ for lighter fermions.

The corresponding higher-order dispersion coefficients, $b_\gamma$, is similarly:

$$b_\gamma = m_\gamma^{d-5} \frac{26}{3} + \cdots; \quad (d = 5)$$

$$= m_\gamma^{d-6} \frac{36}{5} + \cdots; \quad (d = 6)$$

$$= m_\gamma^{d-7} \frac{32}{5} + \cdots; \quad (d = 7)$$

$$= m_\gamma^{d-8} \frac{124}{21} + \cdots; \quad (d = 8)$$

$$= m_\gamma^{d-9} \frac{39}{7} + \cdots; \quad (d = 9)$$

$$= m_\gamma^{d-10} \frac{16}{3} + \cdots; \quad (d = 10); \quad (42)$$

Just as we saw for $d = 4$, $b_\gamma$ always arises at second order in $\alpha$, and so its sign is completely determined in our calculation. As we shall see, the best bound on this coefficient arises when $b_\gamma > 0$.

The above expressions were derived specifically with the scenario of large $\alpha$ at extra dimensions in mind. However, we can also interpret at least the $d = 5$ result in terms of a warped extra dimension. This has more interesting consequences than the case where the quantum gravity scale would have to exceed $M_p > 10^8$ GeV in order to comply with sub-millimeter tests of gravity [23]. In the warped case, even if $M_p > M_5$, the KK gravitons couple to the TeV brane with TeV strength, and they have an mass gap of order TeV. In this model, we live on a TeV brane at $r = r_0$, displaced from the Planck brane at $r = r_0$ such that $M_p = 10^{16}$: in accordance with solving the hierarchy problem. As far as the contributions from the ultraviolet graviton loops are concerned, this looks like quantum gravity with a scale of $M_5$ TeV. The TeV mass gap protects low-energy gravity from any observable distortion, but not so the loop effects from momenta $\propto$ TeV.

V. REAL-WORLD COMPLICATIONS

A further step is required before these results can be compared with the experimental limits on the dispersion relations of real particles. This step involves identifying which low-energy particles produce the largest contributions to any given dispersion relation.

There are two reasons why this additional step is required. First, we would like to apply the above calculations to protons, for which the experimental limit is the strongest. Unfortunately, our calculations treat all fermion masses as an entry, and so can only apply directly to the proton for scales below roughly $m_p = 1$ GeV. Notice these low energies may nonetheless be described by an extra-dimension e-active theory within ADD-type scenarios.) For higher energies, we must apply our calculations to the constituent quarks and gluons, and infer from where the proton dispersion is affected. Unfortunately, the resulting strong-interaction uncertainties prohibit us from following in more detail the 0(1) factors and signs of the results, limiting us to an order-of-magnitude analysis for the proton.

The second reason for being careful in applying our results is the strong dependence which they have on the relevant fermion masses. In particular, it may be that larger contributions are obtained for light particles (like electrons and photons) by embedding the graviton-induced Lorentz-violating contributions of heavier particles (like top quarks) within additional loops. This is how we will recover the larger contributions that might have naively

We thank M. Pospelov for making many very useful suggestions for this and the next sections.
been obtained by keeping the power divergences of the graviton loop graphs.

A. Photons

Our result for the photon dispersion relation is particularly simple, with $c = 1$ for all $d$, and $b = 0$ only for $d = 4$. This simplicity is largely due to our concentrating on the finite and log-divergent contributions, however, which suggests that larger contributions may be found at the (comparatively cheap) expense of introducing additional loops.

For instance, at two loops the photon vacuum polarization acquires contributions by inserting a Lorentz-violating graviton self-energy within a charged-lepton loop (fig. 3). A summing all charged fermions to be bound, and 4-dimesional, we estimate the following results for the photon: $c^2 = 1 - (c^2 - 1)$, giving

$$c^2 = 1 - \frac{4}{(4)^{d-2}} \frac{m_e}{M_d} d^\frac{2}{4} \quad (d = 4)$$

where $d=2$ denotes the integer part of $d=2$ and we use the heaviest known elementary particle, the top quark ($m_t = 175$ GeV), for numerical purposes. Although this is still negligible small for $d = 4$, we shall see that the $d > 4$ result can be large enough to provide new constraints on if $M_d$ is not too far above the TeV range.

A similar contribution arises to $b$, although because of the weaker dependence on $m_t$, the price of a loop factor, $-4$, is not worthwhile when $d = 4$. Here the direct one-loop result of eq. (33) is larger. We expect then

$$b M_d^2 = \frac{304}{15} \frac{3}{8} (d = 4)$$

in four dimensions, where the numerical result uses the conservative estimate $\log(2^{m_{W}} - 1)$. For $d > 4$ we estimate the two-loop result by $b \sim \sqrt{d}$, and so nd:

$$b M_d^2 = \frac{3}{4} \frac{2}{(4)^{d-2}} \frac{m_e}{M_d} d^\frac{4}{4} \quad (d > 4)$$

with $m_t$ being used for the fermion mass. The sign of $b$ and $c^2 = 1$ are not determined by these estimates (although they are certainly calculable with a more careful evaluation of fig. (3)).

B. Electrons

The next-cleanest application of the above analysis is to electrons, since so far we know these are elementary and so our earlier results may be directly applied. Again taking the conservative estimate $\log(2^{m_{W}} - 1)$, we find that the direct graviton-loop contribution to the electron dispersion relation is

$$c^2 = 1 - \frac{4}{(4)^{d-2}} \frac{m_e}{M_d} d^\frac{2}{4} \quad (d = 4)$$

where $d$ counts the number of spacetime dimensions seen by the graviton within the effective theory at scales $< 1$ TeV.

This should be compared with the result of inserting more massive particles into higher loops. For instance, a loop with a $W$ boson and neutrino, with the graviton coupling to the $W$ (fig. 4) gives the alternative contribution

$$c^2 = 1 - \frac{8}{(4)^{d-2}} \frac{m_e}{M_d} d^\frac{4}{4} \quad (d = 4)$$

using $m_W = 80$ GeV, and $\log(2^{m_{W}} - 1)$. This last contribution (for $d = 4$) is always larger than the direct one, eq. (45), because $(m_{ew} \sim m_{e}^{1/2} = 6 \times 10^5 \sim 10^3$).
The higher-loop result can also provide a larger estimate for $h_b$ to wit:

$$h_b M_d^2 = \frac{2}{4} \frac{\pi^2}{(4)^{d/2-1}} \frac{m_w^d}{M_d^d} \quad (d = 5) \quad (49)$$

This dominates the direct one-loop result for all $d \geq 5$, because $(m_\sigma = m_w)^d (4)^{1/2-1} \approx (10)^2 (\text{TeV} = M_5)^2 \approx 3 \times 10^3$.

When $d = 4$ the direct one-loop result wins, for which the results of the previous section give

$$h_b M_4^2 = \frac{12}{8} \quad (d = 4) \quad (50)$$

$$= 2 \times 10^8 \quad 10^2.$$  

$$\begin{align*}
C. \text{ Protons} \\
\text{The direct calculation of section III applies directly for the proton only within the effective theory below a GeV, because it is only within this theory that the proton may be considered to be elementary. For higher scales the relevant degrees of freedom are quarks and gluons, for which we must estimate the size of Lorentz-violating effects.}
\end{align*}$$

The Lorentz-violating gluon and quark contributions may be estimated using our photon and electron results, eqs. (43) and (44), giving:

$$C_q^2 = \frac{1}{4} \left( \frac{\pi}{(4)^{d/2-1}} \right)^{d/2} \frac{m_t}{M_d^d} \quad (d = 5) \quad (53)$$

$$C_g^2 = \frac{1}{4} \left( \frac{\pi}{(4)^{d/2-1}} \right)^{d/2} \frac{m_w}{M_d^d} \quad (d = 5) \quad (54)$$

when $m_\xi = m_t$.

By contrast, for $d = 4$ it is the direct one-loop result which dominates. In this case we have a result for fermions which is largely insensitive to the fermion mass:

$$h_b M_4^2 = \frac{12}{8} \quad (d = 4) \quad (54)$$

$$= 2 \times 10^8 \quad 10^2.$$  

For low-energy gravitons in the effective theory below the proton mass, the proton may be considered to be elementary and eq. (54) can be directly applied to the proton itself.

For higher-energy gravitons, eq. (54) would instead be applied to the light quarks, and the result for the proton would be obtained by taking the matrix element for the resulting effective quark operator, such as $O_q = \frac{1}{4} u \bar{u} u \bar{u} m \@ g \bar{q} \bar{g} \bar{q}$ within the proton. On dimensional grounds this would produce the same result as eq. (54), but potentially with a different numerical coefficient. For concreteness, when comparing with the observables we use eq. (54) including the numerical factor obtained for an elementary proton.

Notice that the above estimates suggest that so long as higher-loop contributions dominate, a hierarchy is to be expected: $j_p \approx j_\bar{p} \approx j_\bar{b} \approx j_\bar{q}$ and $j_b \approx j_\bar{b}$ when $d = 4$, however.

VI. EXPERTMENTAL CONSTRAINTS

We now turn to the experimental constraints which can be imposed on the quantities $c^2$ and $h_b$. Because we are interested in order-of-magnitude bounds, we derive constraints on each of these quantities as if they had arisen in the absence of the other. That is, we consider bounds on $c^2$ while taking $h_b = 0$ and vice versa. This is justified unless there is an unnatural cancellation between the contributions of these quantities to physical observables.

A. Existing Bounds on $c^2$

Good bounds exist on a difference between the propagation speeds of fermions and photons. Among those which do not depend on the sign of $c^2$ are [3]:

$$\begin{align*}
\text{Max}(\frac{5}{8} - 1) \approx 0.19 \\
\left( \frac{5}{8} - 1 \right) \approx 0.19 \\
\left( \frac{5}{8} - 1 \right) \approx 0.19 \\
\left( \frac{5}{8} - 1 \right) \approx 0.19 \\
\left( \frac{5}{8} - 1 \right) \approx 0.19
\end{align*}$$

The loop contributions to $h_b$ can also dominate for large numbers of dimensions, but not for $d = 4$. We have the higher-loop contribution

$$\begin{align*}
h_b M_d^2 &= \frac{2}{4} \frac{\pi^2}{(4)^{d/2-1}} \frac{m_w^d}{M_d^d} \quad (d = 5) \quad (49)
\end{align*}$$

$$\begin{align*}
10^{10} \quad (\text{TeV} = M_5) \quad (d = 5)
\end{align*}$$
In the second bound $c^2$ denotes a particular combination of the Lorentz-violating couplings in\ avor space, whose details are not in your port in what follows.

Although these bounds apply to both signs of $c^2$, they are also subject to specific assumptions which need not apply to our calculation. For instance the bound assumes the existence of Lorentz-violating terms which also violate lepton number, while the bounds involving neutral kaons require strangeness violation in addition to Lorentz-violation. Since the loops which would produce both type of\ avor-symmetry violations from Lorentz-violation in the graviton sector are further suppressed by mass and mixing angles, we do not consider these bounds further.

The bounds from atom\ic spectroscopy are usually derived under the assumption that all BSM particles share the same axion\on propagation speed which differs from that of the photon (i.e., $c_\phi < c$ is independent of $f$). Nevertheless these bounds are likely also to apply if $c_\phi < c$ differs for electrons and nucleons. Although we use the bound of ref. [3] in what follows, we regard a more careful analysis of constraints which are implied by these experiments to be worth pursuing.

If we apply these bounds directly to protons, we need $j \leq 6 \times 10^{-22}$. Using our previous estimates for the proton, eq. (33), and our expectation (see above) that $c^2$ differs from unity by more than does $c^2$, we nd comparision with the bound in ples.

$$< \frac{4}{s} \left( \frac{4}{d^2} \right)^{1.5} \frac{M_d}{m_\tau} \leq 10^{-21}; \quad (56)$$

This is stronger than the direct bound $< 10^{-3}$ only if

$$\frac{M_d}{10^{3} \left( \frac{4}{d^2} \right)^{1.5} \leq 10^{-3}} \leq 3 \times 10^{6} \quad (d = 4); \quad 700 \quad (d = 5); \quad 46 \quad (d = 6). \quad (57)$$

The bound so obtained is not useful for $d = 4$. With extra dimensional gravitons the bound becomes useful only when $M_d$ is very small. It is only of borderline interest for the ADD scenario, for which $d = 6$ but $M_d > 50$ TeV is required from stellar\cooling bounds [28]. We do not quote here the stronger limit coming from the non-observance of gamma-ray decay products [29], or which apply for supersymmetry models because they may be evaded depending on model-dependent details.)

The bound is composite, however, for the warped 5D model described below eq. (44), where $M_5$ is effectively the TeV scale.

### B. Cerenkov Bounds on $b_\pi$ and $c_\pi^2$

We next consider constraints from high-energy cosmic rays, typically protons or photons. Their observation precludes the existence of particles which would too\ciently deplete the energy of these particles. Since the particles involved are at higher energies, these processes are more sensitive to the higher-mom\on\on cients, $b_\pi, b_\phi$, than are low-energy laboratory limits.

Lorentz-violation can introduce dangerous processes by allowing decays in vacuum of the form $p \to p$ or $\gamma e^- e^- \to \gamma e^- e^- e^-$. Such decays are precluded by high-energy cosmic-ray bounds. For instance, the processes $p \to p$ become allowed if the dispersion relation raises the energy of the proton at a given m mom of more than 10 TeV. Similarly, the process $\gamma e^- e^- e^-$ can occur if the photon energy is raised more than the electron's at a given m mom.

As applied to changes in the m aximum propagation speed, the resulting bounds are therefore one-sided, in the sense that they are only relevant for one sign of $c_\pi$ or $c_\phi$. For protons the strong one-sided bound obtained from $p \to p$ requires $c_\pi < 0$. Similarly, for $\gamma e^- e^- e^-$ we nd $c_\phi < 0$. The bound in this way for electrons and protons is

$$2 \times 10^8 < c_\pi^2 < 2 \times 10^{23}$$

In order of m agitude, these bounds are obtained by demanding that $j < m_\pi^2 = E^2$ where $m_\pi$ is the relevant fermion mass, $E$ is the energy of the observed cosmic ray, and the bound only applies to the appropriate sign of $c_\pi^2$. The bound from $p \to p$ is weaker than that from $\gamma e^- e^- e^-$ because the most energetic cosmic-ray proton has $E > 10^4$ TeV, while the most energetic observed gamma-ray has $E > 50$ TeV.

A similar bound also applies to the parameter $b_\phi$, which controls the dispersive part of the dispersion relation, eq. (23). For $p \to p$ the bound then applies only if $b_\phi > b$ and for $\gamma e^- e^- e^-$ it requires $b_\phi < b$. When the bound applies, it is of order $j < b < m_\phi^2 = E^4$.

We nd in this way the constraints

$$j \leq 6 \times 10^{-22} \quad (58)$$

Using the weaker bound $< 10^{-3}$ makes the limits for $M_d$ less by a factor of $10^{-(d-2)}$.\footnote{We use the weaker bound $< 10^{-3}$ to make the limits for $M_d$ less by a factor of $10^{-(d-2)}$.}
\[ (5 \ 10^6 \text{ GeV})^2 < b_p \ b < (3 \ 10^2 \text{ GeV})^2 \]
\[ b_p \ b > (1 \ 10^2 \text{ GeV})^2 : (59) \]

1. \( b_p > b \)

Consider rst the case \( b_p > b \), for which the best bound applies. For \( d > 4 \) we can pare this to the order-of-magnitude higher-loop results, with the resulting expectation \( b_p \ j \ j \ b \ j \). Using eqn. (53) for \( b_p \), as discussed in the previous section, and assuming the sign of the result is the one relevant for the bound's applicability, we obtain the limit

\[\begin{array}{c}
\frac{M_d}{\text{TeV}} < 3 \ 10^3 \ (0.175)^{(d \ 2)^{-2}} \ \frac{r}{(4 \ ^{(d-2)}/2)} \ \frac{m_t}{M_d} \ \frac{M_d}{10^2 \text{ GeV}}
\end{array}\]

This is an improved bound on \( b_p \) for \( d > 4 \). If \( b_p < b \), then the best bound comes from the process \( p \ j \ j \ to\ j \), which does not give a bound even as good as 10 \(^3\) for any \( d \) given the constraint \( M_d > 0 \) TeV.

C. \( b_p < b \)

The bound when \( b_p < b \) is not strong enough to be interesting for \( d = 4 \). Therefore we consider only higher dimensions. Since the order-of-magnitude result for the electron has \( b_p \ j \ j \ we \ have

\[\begin{array}{c}
\frac{b}{M_d < (4 \ ^{(d-2)}/2)} \ \frac{m_t}{M_d} \ \frac{d \ 4}{10^{12} \text{ GeV}}
\end{array}\]

For \( M_d > 1 \text{ TeV} \) this is never better than 10 \(^6\), but it represents progress relative to 10 \(^3\) if

\[\begin{array}{c}
\frac{M_d}{\text{TeV}} < 10^6 \ (0.175)^{(d \ 2)^{-2}} \ \frac{r}{(4 \ ^{(d-2)}/2)} \ \frac{m_t}{M_d} \ \frac{M_d}{10^{12} \text{ GeV}}
\end{array}\]

which is only of interest for 5D warped scenarios.

D. Direct Bounds on \( b \)

The observation of cosmologically distant gamma rays from gamma-ray bursts can provide a bound on \( b \), which is similar in strength to the one just obtained, but applies equally well to both signs of the result. Ref. [17] argues that the absence of dispersion in these signals provides a sensitivity to changes in the photon dispersion which can be as small as

\[\begin{array}{c}
\frac{b}{(9 \ 10^4 \text{ GeV})^2}
\end{array}\]

which would correspond to

\[\begin{array}{c}
\frac{b}{(4 \ ^{(d-2)}/2)} \ \frac{M_d}{m_t} \ \frac{d \ 4}{10^{11} \text{ GeV}}
\end{array}\]

\[\text{In fact, at the energies under consideration the graviton should resolve the proton as a number of partons, each carrying a small momentum fraction } \chi \frac{1}{2}. \text{Since the importance of the dispersive term grows with momentum as } p^2, \text{there will be a suppression } \chi^2. \text{Hence, compared to the photon, the effective } b \text{ for the proton may be close to zero.}\]
This is better than \( \frac{M_4}{\text{TeV}} < 10^5 \) provided

\[
\frac{M_4}{\text{TeV}} < 10^5 \left(0.175^{(d=4)}-2\right) \frac{r}{(4)^{(d=2)}-1} 2-(d=2)
\]

\[
= 20 \quad (d=5)
\]

\[
= 3 \quad (d=6)
\]

which is comparable in strength to what was found above.

VII. CONCLUSIONS

Braneworld scenarios allow the possibility of potentially strong preferred-frame effects arising from extra-dimentional bulk physics, and suggest these effects may be limited to the graviton sector. Depending on their sign, the magnitude of such changes to graviton dispersion can be comparatively large because of the graviton's extremely weak interactions. Motivated by this observation, we have explored how gravitational Lorentz-violation in a braneworld picture influence the properties of observable particles. We obtain the following results:

1. We analyze how Lorentz violation in extra dimensions arises within the low-energy four-dimentional E8i theory which is obtained once the extra dimensions are integrated out. We find the leading contributions to be the appearance of potentialely different metrics in the kinetic term which govern the propagation of the various low-energy particles. If preferred-frame effects dominate violations of translation or rotation invariance (in the preferred frame) then in space the metric seen by particle type \( \kappa \)' may be written

\[
G = + (1, \xi) u u \quad \quad (70)
\]

where \( u \) is the (approximately constant) 4-velocity which defines the preferred frame, \( c_0, m \) may be interpreted as the mass in the propagation speed of this particle type.

2. If subleading contributions at low energies are also included, then more complicated changes to the dispersion relation become possible. For low \( m \) one finds these dispersion relations become \( E_p^2 = p^2 c_0^2 + b_k p^k + \ldots \) in the preferred frame. The next-to-leading coefficient \( b_k \) causes dispersive propagation if it is nonzero. (Odd powers of \( p \), like \( p^3 \), typically do not arise in the dispersion relation since they are usually forbidden by selection rules like rotation invariance in the preferred frame.)

3. Strong observational constraints exist which preclude large differences between the values \( c_0 \) and \( b_k \) for photons and other particles. The strongest of these come from the absence of a dependence on the Earth's velocity through space in atomic spectra, and from the absence of Cerenkov-like decays of very-high-energy cosmic rays.

4. We compute how graviton loops can bring the news of Lorentz violation in the graviton sector to other particles for which stronger constraints exist. We do so quite generally at low energies for the purely massless 4D graviton (the lowest KK mode). We also compute these loops for the entire KK tower of gravitons, in the approximation that the dominant contribution comes from gravitons whose wavelengths are much shorter than the typical curvature scales of the extra-dimentional metric.

5. We find that one-loop contributions to photons from graviton-induced Lorentz violation are small. Keeping the cubic and log-divergent parts, we find gravitons do not induce any change at all in the photon mass in propagation speed, \( c_0 \). The purely 4D graviton induces a dispersive term \( b_k \) in the photon equations of motion which goes to zero at low energies. Unfortunately this makes the strong constraints on photon properties based on gamma-ray bursts and dispersion in quasar signals largely irrelevant to this kind of Lorentz violation.

6. By the same approximations, we find fermions acquire changes to their low-energy dispersion relations with an amount which varies strongly with the fermion's mass. Among the three most abundant particles in everyday life (electrons, protons and photons) this predicts by far the biggest effects for protons. Contributions to \( c_0 \) are linear in \( g_0 \) (if \( g_0 \) is the graviton mass in the propagation speed) while those to \( b_k \) are quadratic in \( g_0 \).

7. The strong mass dependence makes the results very sensitive to the high-energy spectrum of the theory, since heavy particles embedded in higher loops can produce larger contributions to low-energy Lorentz-violating effects than do the direct graviton loops. An estimate of this effect using the top quark or W-boson as the heavy particle suggests that protons receive larger contributions than do photons or electrons.

8. We find that current atomic constraints on \( c_0 \) for observable particles can provide limits on \( c_0 \) which are competitive with the direct bound \( c_0 < 10^{-6} \) arising from Newtonian corrections in the solar system, but only if \( d = 5 \) or 6 and if the higher-dimentional Planck mass, \( M_d \), is as close as possible to the TeV scale. For instance, for a warped \( d = 5 \) model with \( M_5 = 10 \) TeV, we find \( b_0 \approx 1 \) is predicted by the direct bound \( c_0 < 10^{-6} \) to be \( 1 < 10^{-5} \) provided \( M_5 \leq 700 \) TeV.

8. We find that stronger constraints on \( c_0 \) arise from limits on \( b_0 \), depending on the dimension of the extra-dimentional spacetime, and on how low the d-dimentional Planck scale, \( M_d \), is. Lower values of \( M_d \) lead to better bounds, which can go up to values of order \( M_d \approx 10^7 \) TeV (for \( d = 5 \)) provided that \( b_0 > b_k \), the sign of this quantity is important, because the bounds which are most constraining are those which are based
on the absence of too-efficient energy-loss mechanisms for the highest energy cosmic rays (which we take to be protons), and the decay channel $p^+ p^-$ is only open if $b_p > b$. Strikingly, purely 4-dimensional graviton loops can give contributions with the right sign, and which are large enough to produce bounds which are of order $< 7 \times 10^4$. This makes them comparable with those from obtained from terrestrial experiments and the binary pulsar.

Perhaps our most surprising result is that, in some regions, graviton loops are already being constrained by observational data. This is yet another striking way in which the brane-world picture can run against pre-brane-world intuition.

VIII. Appendix A

In this appendix we record the expressions for the Feynman rules for the photon-graviton vertex, as obtained from the Einstein-Maxwell action, eq. (4). One finds:

\[ V^{(P;Q)} = (P \cdot Q) = (P \cdot Q) + (P \cdot Q) + (P \cdot Q) + (P \cdot Q); \]

which has the required symmetry properties:

\[ V^{(P;Q)} = V^{(Q;P)} = V^{(P;Q)} : \quad (Q;P) : \]

IX. Appendix B

We here record in more detail the results of the fermion self-energy calculation, using a graviton loop in d dimensions.

\[ A_d = \frac{\alpha}{\pi} \left( \frac{1}{2} \right)^{d-2} \left( \frac{\alpha}{\pi} \right)^{d-2} \]

For six spacetime dimensions evaluation of the graviton loop gives

\[ A_6 = m^2 \left( \begin{array}{c} 25 \\frac{9}{2} \\frac{9}{2} \\frac{9}{2} \\frac{9}{2} \end{array} \right) \]

\[ B_6 = m^2 \left( \begin{array}{c} 35 \\frac{18}{2} \\frac{18}{2} \\frac{18}{2} \\frac{18}{2} \end{array} \right) \]

\[ C_6 = m^2 \left( \begin{array}{c} 25 \\frac{6}{2} \\frac{6}{2} \\frac{6}{2} \\frac{6}{2} \end{array} \right) \]

\[ D_6 = m^2 \left( \begin{array}{c} 101 \\frac{30}{2} \\frac{30}{2} \\frac{30}{2} \\frac{30}{2} \end{array} \right) \]

\[ E_6 = m^2 \left( \begin{array}{c} 29 \\frac{30}{2} \\frac{30}{2} \\frac{30}{2} \\frac{30}{2} \end{array} \right) \]

where $s = (s = 8)^2$. The result is nine in dimensional regularization because one-loop results in odd dimensions always are with this regularization scheme. This result agrees with the nine part as computed by directly cutting the momentum integrals and ignoring the divergent term $s$ (none of which are logarithmically divergent). These lead to the dispersion relation of eq. (73):

\[ \alpha_2 \alpha_4 = m^3 \left( \begin{array}{c} 110 \\frac{9}{2} \\frac{9}{2} \\frac{9}{2} \\frac{9}{2} \end{array} \right) \]

\[ \alpha_4 \alpha_4 = m^3 \left( \begin{array}{c} 26 \\frac{3}{2} \\frac{3}{2} \\frac{3}{2} \\frac{3}{2} \end{array} \right) \]

Notice that both of these results are positive (provided $\alpha > 0$).

B. $d = 6$

For six spacetime dimensions the graviton loop gives

\[ A_6 = m^2 \left( \begin{array}{c} 9 \\frac{4}{2} \\frac{4}{2} \\frac{4}{2} \\frac{4}{2} \\frac{4}{2} \\frac{4}{2} \end{array} \right) \]

\[ B_6 = m^2 \left( \begin{array}{c} 6 \\frac{30}{2} \\frac{30}{2} \\frac{30}{2} \\frac{30}{2} \\frac{30}{2} \\frac{30}{2} \end{array} \right) \]

\[ C_6 = m^2 \left( \begin{array}{c} 18 \\frac{15}{2} \\frac{15}{2} \\frac{15}{2} \\frac{15}{2} \\frac{15}{2} \\frac{15}{2} \end{array} \right) \]

\[ D_6 = m^2 \left( \begin{array}{c} 34 \\frac{15}{2} \\frac{15}{2} \\frac{15}{2} \\frac{15}{2} \\frac{15}{2} \\frac{15}{2} \end{array} \right) \]

\[ E_6 = m^2 \left( \begin{array}{c} 4 \\frac{3}{2} \\frac{3}{2} \\frac{3}{2} \\frac{3}{2} \\frac{3}{2} \\frac{3}{2} \end{array} \right) \]

where $s = 2^{1/2} = 2^3 L$. As before $L = \log(2^n - 2) = 2^3$ (when evaluated with an ultraviolet cut-off, and in dimensional regularization). These lead to the $d = 6$ results:
Again both results are positive for \( d > 0 \).

**C.** \( d = 7 \)

Next, seven spacetime dimensions:

\[
\begin{align*}
A_7 &= m^6 \gamma \left( \frac{49}{25} + \frac{26}{25} + \frac{129}{25} \right)^2 + \cdots ; \\
B_7 &= m^5 \gamma \left( \frac{21}{25} + \frac{131}{70} \right)^2 + \cdots ; \\
C_7 &= m^4 \gamma \left( \frac{49}{15} + \frac{263}{42} \right)^2 + \cdots ; \\
D_7 &= m^3 \gamma \left( \frac{59}{35} \right)^2 + \cdots ; \\
E_7 &= m^2 \gamma \left( \frac{53}{35} \right)^2 + \cdots ;
\end{align*}
\]

where \( \gamma = \frac{2}{3} = [6(4)^4] \), and is finite when evaluated in dimensional regularization.

These lead to the \( d = 7 \) results:

\[
\begin{align*}
C_7^2 &= 1 = m_0^6 \gamma \left( \frac{616}{75} + \frac{244}{15} \right)^2 + \cdots ; \\
\beta &= m_0^3 \gamma \left( \frac{32}{5} \right)^2 + \cdots ;
\end{align*}
\]

Here both results are negative for \( d > 0 \).

**D.** \( d = 8 \)

For eight spacetime dimensions we have

\[
\begin{align*}
A_8 &= m^7 8 \left( \frac{16}{9} + \frac{41}{32} + \frac{77}{18} \right)^2 + \cdots ; \\
B_8 &= m^6 8 \left( \frac{40}{63} + \frac{173}{126} \right)^2 + \cdots ; \\
C_8 &= m^5 8 \left( \frac{64}{21} + \frac{239}{42} \right)^2 + \cdots ; \\
D_8 &= m^4 8 \left( \frac{4}{3} \right)^2 + \cdots ; \\
E_8 &= m^3 8 \left( \frac{34}{21} \right)^2 + \cdots ;
\end{align*}
\]

where \( \gamma = 2 = [8(4)^4] L \). As before, \( L = \log(2^2) = 2 = [8(4)^4] \), when evaluated with an ultraviolet cutoff, and in dimensional regularization.

These lead to the \( d = 8 \) results:

\[
\begin{align*}
C_8^2 &= 1 = m_0^6 \gamma \left( \frac{464}{63} + \frac{890}{63} \right)^2 + \cdots ; \\
\beta &= m_0^3 \gamma \left( \frac{124}{21} \right)^2 + \cdots ;
\end{align*}
\]

Here both results are positive for \( d > 0 \).

**E.** \( d = 9 \)

For \( d = 9 \) we have

\[
\begin{align*}
A_9 &= m^8 9 \left( \frac{81}{49} + \frac{202}{49} + \frac{181}{49} \right)^2 + \cdots ; \\
B_9 &= m^7 9 \left( \frac{99}{196} + \frac{3755}{3528} \right)^2 + \cdots ; \\
C_9 &= m^6 9 \left( \frac{81}{28} + \frac{2665}{504} \right)^2 + \cdots ; \\
D_9 &= m^5 9 \left( \frac{277}{252} \right)^2 + \cdots ; \\
E_9 &= m^4 9 \left( \frac{425}{252} \right)^2 + \cdots ;
\end{align*}
\]

where \( \gamma = \frac{2}{3} = [15(4)^4] \).

These lead to the results:

\[
\begin{align*}
C_9^2 &= 1 = m_0^7 9 \left( \frac{333}{49} + \frac{1245}{98} \right)^2 + \cdots ; \\
\beta &= m_0^5 9 \left( \frac{39}{7} \right)^2 + \cdots ;
\end{align*}
\]

Here both results are positive for \( d > 0 \).

**F.** \( d = 10 \)

Finally, for ten spacetime dimensions:

\[
\begin{align*}
A_{10} &= m^9 10 \left( \frac{25}{16} + \frac{61}{16} + \frac{105}{32} \right)^2 + \cdots ; \\
B_{10} &= m^8 10 \left( \frac{5}{12} + \frac{103}{120} \right)^2 + \cdots ; \\
C_{10} &= m^7 10 \left( \frac{25}{9} + \frac{449}{90} \right)^2 + \cdots ; \\
D_{10} &= m^6 10 \left( \frac{14}{15} \right)^2 + \cdots ; \\
E_{10} &= m^5 10 \left( \frac{26}{15} \right)^2 + \cdots ;
\end{align*}
\]

where \( \gamma = 2 = [3(8)^5] L \), and \( L = \log(2^2) = 2 = [10(4)^4] \), when evaluated with an ultraviolet cutoff, and in dimensional regularization.

These lead to the \( d = 10 \) results:
\[ C_f = \frac{m_f^5}{18} \left( \frac{115}{18} + \frac{421}{36} \right) z + \cdots ; \]
\[ b_r = \frac{m_r^7}{10} \left( \frac{16}{3} \right) z^2 + \cdots ; \]

> 0 ensures that both results in this case are positive.

18. [S. W. Weinberg, Gravitation and Cosmology, John Wiley & Sons, 1972.]
