A high precision measurement of the transverse spin-dependent asymmetry $A_T$ in $^3$He$(e,e')$ quasielastic scattering was performed in Hall A at Jefferson Lab at values of the squared four-momentum transfers $Q^2$, between 0.1 and 0.6 (GeV/c$^2$). $A_T$ is sensitive to the neutron magnetic form factor, $G^n_M$. Values of $G^n_M$ at $Q^2 = 0.1$ and 0.2 (GeV/c$^2$) were extracted using Faddeev calculations, were reported previously. Here, we report the extraction of $G^n_M$ for the remaining $Q^2$-values in the range from 0.3 to 0.6 (GeV/c$^2$) using a Plane-Wave Impulse Approximation calculation. The results are in good agreement with recent precision data from experiments using a deuteron target.

form factor, \( G_M^n \), and the magnetic form factor, \( G_E^n \), has become a focus of experimental activity. Considerable attention has been devoted to the precise measurement of \( G_M^n \). While knowledge of \( G_M^n \) is interesting in itself, it is also required for the determination of \( G_E^n \), which is usually measured via the ratio \( \frac{G_M^n}{G_E^n} \). Furthermore, precise data for the nucleon electron magnetic form factors are essential for the analysis of parity violation experiments designed to probe the strangeness content of the nucleon.

Until recently, most data on \( G_M^n \) had been deduced from elastic and quasi-elastic electron-deuteron scattering. For inclusive \( G_M^n \) measurements, this procedure requires the separation of the longitudinal and transverse cross sections and the subsequent subtraction of a large proton contribution. Thus, it suffers from large theoretical uncertainties due in part to the deuteron model employed and in part to corrections for final-state interactions (FSI) and meson-exchange currents (MEC). These complications can largely be avoided if one can measure the cross-section ratio of de (\( e\bar{e}p^n \)) to de (\( e\bar{e}p^p \)) at quasi-elastic kinematics. Several recent experiments have employed this technique to extract \( G_M^n \) with uncertainties of < 2% at \( Q^2 \) below 1 GeV/c^2. Despite the high precision reported, however, there is considerable disagreement among some of the experiments with respect to the absolute value of \( G_M^n \). The most recent deuteron data further emphasize this discrepancy.

Thus, additional data on \( G_M^n \), preferably obtained using a common electron beam method, are highly desirable. Inclusive quasi-elastic \( ^3\)He (e, \( e'p^p \)) scattering provides just such an alternative approach. In combination with deuteron experiments, this technique employs a direct target and relies on polarization degrees of freedom. It is thus subject to completely different systematics. A recent constrained recent \( ^3\)He experiment, a precision parable to that of deuteron ratio experiments can be achieved with the \( ^3\)He technique.

The sensitivity of spin-dependent \( ^3\)He (e, \( e'p^p \)) scattering to neutron structure originates from the cancellation of the proton spins in the dominant spatially symmetric wave of the \( ^3\)He ground state. As a result of this cancellation, the spin of the \( ^3\)He nucleus is predominantly carried by the unpaired neutron alone [9,10]. Hence, the spin-dependent contributions to the \( ^3\)He (e, \( e'p^p \)) cross section are expected to be sensitive to neutron properties. From this, the spin-dependent part of the inclusive cross section is contained in two nuclear response functions, a transverse response \( R_T \) and a longitudinal-transverse response \( R_{TL} \), which occur in addition to the spin-independent longitudinal and transverse responses \( R_L \) and \( R_T \)[1]. \( R_T \) and \( R_{TL} \) can be isolated experimentally by demanding the spin-dependent asymmetry \( A \) defined as \( A = (h^+ - h^-)/(h^+ + h^-) \), where \( h \) denotes the cross section for the two different helicities of the polarized electrons. In terms of the nuclear response functions, \( A \) can be written [11]

\[
A = \frac{(\cos T^i R_T + 2 \sin T^i R_{TL})}{\cos T^i R_T + \cos T^i R_{TL}}
\]

where the \( k \) are kinematic factors and \( T^i \) are the polar and azimuthal angles of target spin with respect to the 3-momentum transfer vector \( q \). The response functions \( R_k \) depend on \( Q^2 \) and the electron energy transfer \( \lambda \). By choosing \( \lambda = 0 \), i.e., by orienting the target spin parallel to the m onentum transfer vector \( q \), one selects the transverse momentum \( T^i \) (proportional to \( R_T \)). Various detailed calculations have confirmed that \( R_T \), and thus \( A \), is strongly sensitive to \( G_M^n \).

The experiment was carried out at Hall A at the Thomas Jefferson National Accelerator Facility (JLab), using a longitudinally polarized continuous-wave electron beam incident on a high-pressure polarized \( ^3\)He gas target [12]. Six kinematic points were measured corresponding to \( Q^2 = 0.1 \) to 0.6 (GeV/c)^2 in steps of 0.1 (GeV/c)^2. An incident electron beam energy, \( E_i \), of 0.778 GeV was employed for the two lowest \( Q^2 \) values of the experiment, while the remaining points were obtained at \( E_i = 1.727 \) GeV. The spectrometer settings of the six quasi-elastic kinematic points are listed in Table I. To maximize the sensitivity to \( A \), the target spin was oriented at 625° to the right of the incident electron m onentum direction. This corresponds to from 85 to 6°, resulting in a contribution to the asymmetry due to \( R_{TL} \) of less than 2% at all kinematic settings, as determined from plane-wave impulse approximation (PWIA) calculations. Further experimental details can be found in references [9,19,20].

Results for \( A \) (Fig. 1) as a function of \( Q^2 \) for all six kinematic points of this experiment are given together with the extracted \( G_M^n \) values at the two lowest \( Q^2 \) kinematic points of the experiment were reported previously [11]. A state-of-the-art non-relativistic Faddeev calculation [21] was employed in the extraction of \( G_M^n \) at these two \( Q^2 \) kinematic points. As discussed in [11], this calculation, while very accurate at low \( Q^2 \), is not believed to be sufficiently precise for a reliable extraction of \( G_M^n \) from the \( ^3\)He asymmetry data at higher \( Q^2 \) because of its non-relativistic nature. Thus, it was not used to extract \( G_M^n \) for \( Q^2 \) values of 0.3 and 0.4

**Table I.** The spectrometer settings for the six quasi-elastic kinematic points of the experiment, where \( E_i \) is the incident electron beam energy, \( E_f \) and \( A \) are the spectrometer central momentum and scattering angle settings, respectively.
In light of this, we felt it was reasonable to extract $G_M^3$ from our asymmetry data using PWIA. In order to estimate the model uncertainty of this procedure, we used results from the full Faddeev calculation up to a $Q^2$ value of 0.4 (GeV/c)$^2$ to study quantitatively the size and $Q^2$-dependence of FSI and MEC corrections. A recent PWIA calculation \cite{14} which takes into account the relativistic kinematics and current using the AV18 NN interaction potential and the H"ohler nucleon form factor parameterization \cite{23} (for the proton form factors and $G_M^3$) was used for the extraction of $G_M^3$ at $Q^2 = 0.3$ (GeV/c)$^2$. In this calculation, the struck nucleon is described by a plane wave, and the interaction between the nucleons in the spectator pair is treated exactly by including the NN and the Coulomb interaction between the pp pair. The de Forest CCI o-shell prescription \cite{24} was adopted for the electron-nucleon cross section. Furthermore, the Urbana IX three-body forces \cite{25} were included in the $^3$He bound state.

To extract $G_M^3$, measured transverse asymmetry data from a 30 MeV region around the quasielastic peak were used. The PWIA calculation \cite{14} was employed to generate $A_{T:3}$ as a function of $G_M^3$ in the same 30 MeV-wide region. In doing so, spectrometer acceptance effects were taken into account. By comparing the measured asymmetries with the PWIA predictions, $G_M^3$ values could be extracted. Results for $G_M^3$ were obtained in two ways: (a) by taking the weighted average of $A_{T:3}$ from three neighboring 10 MeV bins around the quasielastic peak (30 MeV total) and then extracting $G_M^3$ from this average asymmetry, and (b) by first extracting $G_M^3$ from each of these 10 MeV bins separately and then taking the weighted average of the resulting $G_M^3$ values. Both methods yield essentially the same results (within 0.1%).

The systematic uncertainty in $G_M^3$ is almost entirely due to the systematic error from the determination of the beam and target polarizations, which is 1.7% in $A_{T:3}$ and 0.8% in $G_M^3$. Such a high precision in the determination of beam and target polarizations can be achieved by using elastic polarization. An additional systematic error occurs in the extraction of $G_M^3$ due to the experimental uncertainty in the determination of the energy transfer $\omega$. The uncertainty due to this source is 1.4% at $Q^2 = 0.3$ and becomes negligible (< 0.5%) at the higher $Q^2$ points.

The model uncertainty inherent in the extraction procedure depends on the various ingredients of the calculation, such as the NN potential, the proton nucleon form factors, relativity, and the reactions mechanism, including FSI and MEC. The main processes neglected in PWIA are FSI and MEC; therefore, these two contributions are expected to dominate the overall model uncertainty. As mentioned, we used results from the non-relativistic Faddeev calculation carried out up to a $Q^2$ value of 0.4 (GeV/c)$^2$ to estimate the uncertainties resulting from the.

\(\text{(GeV/c)}^2\) even though the Faddeev calculation has been extended numerically to a $Q^2$ value up to 0.4 (GeV/c)$^2$. The high precision $^3$He quasielastic asymmetry data in the breakup region from the same experiment \cite{22} at $Q^2$ values of 0.1 and 0.2 (GeV/c)$^2$ provided stringent test of the Faddeev calculation and supported further the approach used in Ref. \cite{23} in extracting $G_M^3$ at $Q^2$ values of 0.1 and 0.2 (GeV/c)$^2$. Thus, a fully relativistic three-body calculation is highly desirable for a reliable extraction of $G_M^3$ at higher values of $Q^2$. Unfortunately, such a calculation is not available and difficult to carry out at present time.

On the other hand, the size of FSI and MEC corrections to inclusive scattering data is well-known to diminish with increasing momentum transfer, and so PWIA will likely describe the data well at higher $Q^2$. Indeed as shown in Fig. 1, the PWIA \cite{14} calculation provides an excellent description of the data at $Q^2$ values of 0.5 and 0.6 (GeV/c)$^2$. In light of this, we felt it was reasonable to extract $G_M^3$ from our asymmetry data using PWIA.
Based on the Faddeev calculation [17], we find that the MEC effect is of 1-2% for the standard dipole form factor (1 + Q^2/0.71)^2, at Q^2 values of 0.3 to 0.6 (GeV/c)^2 extracted using PWIA calculations. Also shown are published measurements since 1990 and a few selected theoretical models. The Q^2 points of Anklüg [9] and Gao 94 [8] have been shifted slightly for clarity. The solid curve is a recent cloudy bag model calculation [31], the long dashed curve is a recent calculation based on a fit of the proton data using dispersion theory arguments [32], and the dotted curve is a recent analysis based on the vector meson dominance model [30]. The dashed curve is a skyrmion soliton model calculation [33], and the dash-dotted curve is a relativistic quark model calculation [34].

To estimate the effect of FSI and MEC, (Faddeev results for Q^2 > 0.4 were not generated because the calculation manifestly breaks down in that kinematic region.)

To estimate the effect of FSI, the non-relativistic Faddeev calculation with FSI, corrected for relativistic effects, was compared with the relativistic PWIA calculation [14]. Relativistic corrections to the Faddeev calculation were derived from a comparison between the standard, relativistic PWIA calculation [14] and a modified, non-relativistic PWIA calculation [13]. One can thus study the size and the Q^2-dependence of the FSI effect up to a Q^2 value of 0.4 (GeV/c)^2. As expected, FSI corrections to A_{T,e} decrease with increasing Q^2. The estimated errors in A_{T,e} due to the neglect of the FSI effect in PWIA are 9.0%, 3.6% for Q^2 = 0.3, 0.4, and on the order of 1-2% for Q^2 values of 0.5, and 0.6 (GeV/c)^2 based on an extrapolation beyond a Q^2 value of 0.4 (GeV/c)^2.

The MEC effect can be addressed in a similar manner. Based on the Faddeev calculation [17], we find that MEC corrections to A_{T,e} near the top of the quasi-elastic peak decrease exponentially as Q^2 increases. Similar conclusions have been drawn from studies of the quasi-elastic d(e,e'p) process [35]. We estimate the uncertainty due to the neglect of the MEC effect in PWIA for A_{T,e} on top of the quasi-elastic peak to be 3.6%, 2.4%, 1.0%, and 1.0% for Q^2 of 0.3, 0.4, 0.5, and 0.6 (GeV/c)^2, respectively.

The effect of various skew-shell prescriptions [27] was studied in the framework of the PWIA calculation, and the contribution to the uncertainty of extracting G^0_M from A_{T,e} was found to be negligible. Difference in G^0_M arising from different choices of NN potential and other nucleon form factor parametrizations was found to be about 1%.

Results for G^0_M extracted at Q^2 = 0.3 to 0.6 (GeV/c)^2 using the PWIA calculation are presented in Table II along with statistical, systematic, and model uncertainties. The model uncertainties are obtained based on studies described previously, which may represent the lower limit only. The results are plotted in Fig. 2 along with the previously reported G^0_M results [9] at Q^2 = 0.1 and 0.2 (GeV/c)^2, which were extracted using the Faddeev calculation. All other published results since 1990 are also shown. The error bars shown on our data are the quadrature sum of the statistical and systematic uncertainties reported in Table II, which do not include the estimated model uncertainty.

In conclusion, we have measured the spin-dependent asymmetry A_{T,e} in the quasi-elastic d(e,e'p) process with high precision at Q^2-values from 0.1 to 0.6 (GeV/c)^2. In this Rapid Communication, we report the extraction of G^0_M at Q^2 values of 0.3 to 0.6 (GeV/c)^2 based on PWIA calculations, which are expected to be reasonably reliable in our range of Q^2. We estimate the total uncertainty of our results to be about 4-6%. More precise extraction of G^0_M at these Q^2 values requires a fully relativistic three-body calculation, which is unavailable at present. Efforts are underway to extend the theory into this regime [36].

We thank the Hall A technical staff and the J. E. Larson Lab Accelerator Division for their outstanding support during this experiment. This work was supported by the U.S. Department of Energy, DOE/EPSCOR, the U.S. National Science Foundation, the Science and Technology Cooperation Germany-Poland, and the Polish-Mathematical Institute.
ish Committee for Scientific Research, the Ministero dell'Università e della Ricerca Scientifica e Tecnologica (Musr), the French Commissariat à l'Energie Atomique, Centre National de la Recherche Scientifique (CNRS) and the Italian Istituto Nazionale di Fisica Nucleare (INFN). This work was supported by DOE contract DE-AC05-84ER40150 under which the Southeastern Universities Research Association (SURA) operates the Thomas Jefferson National Accelerator Facility. The numerical calculations were performed at the U.S. National Energy Research Scientific Computer Center (NERSC) and NIF in July.
