Abstract

We give a new derivation of the quasinormal frequencies of Schwarzschild black holes in $d = 4$ and Reissner-Nordström black holes in $d = 4$, in the limit of infinite damping. For Schwarzschild in $d = 4$ we find that the asymptotic real part is $T_{\text{Hawking}} \log(3)$ for scalar perturbations and for some gravitational perturbations; this conforms to a result previously obtained by other means in the case $d = 4$. For Reissner-Nordström in $d = 4$ we find a specific generally aperiodic behavior for the quasinormal frequencies, both for scalar perturbations and for electromagnetic-gravitational perturbations. The formulas are obtained by studying the monodromy of the perturbation analytically continued to the complex plane; the analysis depends essentially on the behavior of the potential in the "unphysical" region near the black hole singularity.
1 Introduction: why do we study quasinormal modes?

Recently it has been proposed [1] that the asymptotic behavior of the high overtone black hole quasinormal frequencies captures information about the spectrum of black hole observables and about quantum gravity in general. More precisely, it has been suggested that the asymptotic real part of the black hole quasinormal frequencies coincides with the frequency emitted by a black hole whose area decreases by an amount that is natural from the point of view of discrete approaches to quantization of gravity such as loop quantum gravity (LQG). While such approaches remain highly speculative, it is nevertheless interesting to understand how far this argument can be pushed; moreover, even if this particular line of inquiry has to be abandoned, the asymptotic spectrum of black hole excitations is a fundamental property of the black hole which should eventually be good for something. This paper is an attempt to simplify and extend the calculations of the relevant experimental data.

Let us briefly review the recent developments in loop quantum gravity which have led us to investigate this asymptotic spectrum. (See [2, 3, 4] for increasingly lengthy reviews of LQG and [5, 6] for the original derivations of the area quantization law in LQG.) In LQG, the natural quantum $A_0$ of the horizon's area is proportional to the so-called Barbero-Immirzi parameter [7, 8], a parameter in LQG which is arbitrary from the point of view of the microscopic definition of the theory, but whose value must be chosen in such a way that the black hole entropy comes out correctly. This comes about as follows: one imagines that each quantum of area $A_0$ carries a piece of discrete information. It can be found in different microstates, and therefore it carries entropy $\log k$. This must be equal to the known contribution of this area quantum to the black hole entropy, namely $A_0=4G$, so we find that

$$A_0 = 4G \log k: \quad (1)$$

LQG predicts that $k = 2J^{(m \downarrow)} + 1$, where $J^{(m \downarrow)}$ is the minimal allowed spin carried by the spin networks. This means that $k = 2$ if the basic gauge group of LQG is taken to be $SU(2)$, or $k = 3$ if the gauge group is $SO(3)$. However, from the LQG point of view there seems to be no reason to choose this strange number $\log(2)$ or $\log(3)$ (more precisely, $\log(2) = \log(3) = 1$ for the Barbero-Immirzi parameter).

On the other hand, seemingly unrelated, one can consider the quasinormal modes of the black hole background. Quasinormal modes are pertur-
perturbations of the background which are allowed to have complex frequency but whose boundary conditions must be \textquoteleft purely outgoing\textquoteright both at the horizon and at infinity; we will review their precise definition in Section 2. This boundary condition singles out discrete complex frequencies \( \beta_n \). As \( \beta_n \neq 1 \), the quasinormal frequencies of gravitational perturbations are known to behave as

\[ \beta_n = T_{\text{Hawking}}(2 \ln 1 - 2) + \log(3); \quad (2) \]

(Varying from the usual convention in general relativity, we parametrize the frequencies in terms of \( T_{\text{Hawking}} \), which is equal to \( 1 = 8 \) M G for a four-dimensional Schwarzschild black hole.) The imaginary part of (2) is not hard to understand. The quasi-normal modes determine the position of poles of a Green's function on the given background, and the Euclidean black hole solution converges to a thermaldisc at infinity with the inverse temperature \( T = T_{\text{Hawking}} \); therefore it is not too surprising that the spacing of the poles in (2) coincides with the spacing \( 2 i T_{\text{Hawking}} \) expected for a thermal Green's function.

However, we are not aware of a similar classical explanation of the term \( \log(3) \) in (2). This term is remarkable because, as was first observed in \([1]\), it is precisely the same strange number one needs to occur in the Barbero-Immirzi parameter of LQG if the gauge group is taken to be SO(3). There are also some heuristic arguments which suggest that there might indeed be a reason to relate the two, identifying the quasi-normal mode with a process in which the black hole ejects a single spin-network edge and thus reduces its area by \( A_0 \).

The result (2) was originally obtained by numerical calculations ten years ago \([9, 10, 11, 12]\). At that time the term \( \log(3) \) was only known to an accuracy of six decimal places. In 1998, Hod conjectured \([13]\) that this number was exactly \( \log(3) \). His conjecture was recently proven in \([14]\), using the methods of continued fractions initiated by Leaver \([9]\) and further refined by Nollert \([10]\).

In this paper we would like to reproduce the results of \([14]\), using simpler functional methods which also allow us to extend the analysis to the cases of charged and higher-dimensional black holes. We will find that the answer \( T_{\text{Hawking}} \log(3) \) is in fact universal for Schwarzschild black holes in all dimensions, at least for scalar and some gravitational perturbations. For Reissner-Nordström in \( d = 4 \) we will find a more complicated generically aperiodic behavior, both for scalar and electromagnetic-gravitational perturbations.

Our computation depends on an analytic continuation in the radial coor-
dinate \( r \), so it is worth mentioning that analytic continuation in \( r \) has been applied to the determination of quasi-normal modes many times before; in particular, it was the basis of the numerical calculations in [11] which confirmed that \( \text{Re} \ log(3) \) for Schwarzschild. A review of the use of complex coordinate methods to compute black hole quasi-normal frequencies has recently appeared in [15], to which we refer the reader for more extensive references. We note that in our calculation of the leading-order asymptotic frequencies no phase integral technology will be required; it will be enough to use simply the first-order WKB approximation.

We believe that this puzzling behavior of the Green’s functions at large imaginary frequencies should contain some important information about black holes and perhaps even quantum gravity.

2 Quasi-normal frequencies for \( d = 4 \) Schwarzschild black holes

2.1 The differential equation

In this section we will be concerned with properties of certain perturbations of a four-dimensional Schwarzschild geometry, described by solutions of the differential equation [16]

\[
1 + \frac{1}{r} \frac{\partial^2}{\partial r^2} + V(r) \frac{1}{r^2} (r) = 0
\]

(3)

on the interval \( 1 < r < \infty \), with the "Regge-Wheeler" potential

\[
V(r) = 1 + \frac{1}{r} \left( \frac{1}{r^2} + \frac{1}{r^3} \right) =: \]

(4)

The equation (3) describes the radial dependence of a spin-\( j \) perturbation of the background, with orbital angular momentum and time dependence \( e^{it} \). We have set \( 2GM = 1 \); in these units the horizon is at \( r = 1 \).

The numerator \( 1 - \frac{1}{r^2} \) which appears in (4) characterizes the spin \( j \) of the perturbation for \( j = 0,1,2 \), i.e., for perturbations by scalar or electromagnetic test fields as well as perturbations of the metric itself. (Actually, in the cases \( j = 1,2 \), one has to expand in tensor spherical harmonics and then (4) is only correct if we consider an "axial" perturbation; see e.g. [18].) It is nevertheless interesting to study the problem for general \( j \), because our calculation relates this coefficient to Bessel’s equation and shows that it
is very natural to write the numerator in this form. It might be useful to summarize its values for the most important examples of $j$:

\[
\begin{array}{ccc}
8 & < & 1: \text{ scalar perturbation} \\
1 & j^2 = & 0: \text{ electromagnetic perturbation} \\
3 & 2 & 1: \text{ gravitational perturbation}
\end{array}
\]

The factor $1 \frac{1}{r}$ which occurs in (3), (4) is the "warp factor" in the Schwarzschild geometry, which in Schwarzschild coordinates is simply the time component $g_{00}$ of the metric.

We wish to study (3) on the physical region $1 < r < 1$ and we begin by describing the asymptotic solutions. To simplify the differential operator which appears it is convenient to define the "tortoise coordinate" $x$ with the property that

\[
dx = 1 \frac{1}{r} \, dr:
\]

Integrating (6) gives

\[
x = r + \log(r - 1):
\]

Then $x$ takes values $1 < x < 1$, and (3) becomes

\[
\frac{\theta^2}{\partial x^2} + V[r(x)] \, \theta^2 = 0:
\]

Since $V[r(x)] \neq 0$ as $x \to 1$, the solutions behave as $e^{i \mu x}$ at infinity.

2.2 Analytic continuation

In our analysis we will find that it is essential to extend (3) beyond the usual physical region $1 < r < 1$. Continued to the whole complex $r$-plane, (3) is an ordinary differential equation with regular singular points at $r = 0$, $r = 1$ and an irregular singular point at $r = 1$; and by the general theory of differential equations, any solution of (3) in the physical region extends to a solution on the $r$-plane. However, this solution may be multivalued around the singular points $r = 0$, $r = 1$. This multivaluedness will play a crucial role in our analysis, which is essentially concerned with the computation of the monodromy around a particular closed contour in the $r$-plane. For convenience, to avoid having to deal with multivalued functions, we can put branch cuts in the $r$-plane from $r = 0$ and $r = 1$ and require that $r \equiv r$ satisfy (3) everywhere except at the cuts. In this approach the monodromy is defined by the discontinuity across the cut.
We will find it very convenient to exploit the simpler representation (8) for the differential equation. After passing to complex \( r \) this introduces an extra complication, since the relation (7) between \( x \) and \( r \) is itself multivalued because of the term \( \log(r - 1) \). As a result, as we travel around a contour in the \( r \)-plane, the corresponding contour in the \( x \)-plane may not be closed. In the language of branch cuts we would say that \( x \) jumps when \( r \) crosses the branch cut which emanates from \( r = 1 \).

Although \( x \) is not uniquely defined as a function of \( r \), the ambiguity is only in the imaginary part, so \( R e x \) still makes sense. It will be important for us to know the sign of \( R e x \) in the various regions of the \( r \)-plane; the structure is as shown in Figure 1. We also show a convenient choice of branch cuts (to economize, one should take the branch cut to be the same for \( (r) \) and for \( \log(r - 1) \)) although nothing we say will depend on this choice.

### 2.3 Definition of quasinormal modes

Because the potential \( V(r) \) is positive and decays to zero at both ends, there are no discrete normalizable bound states. Nevertheless we may look for discrete quasinormal states, counterparts of quasistationary states in quantum mechanics because their frequency is also allowed to be complex. The mathematical theory of these quasinormal modes is more intricate than for ordinary normal modes; see e.g. [20] for a more precise discussion than we will give here, as well as an excellent review of the substantial literature on quasinormal modes of black holes.

Roughly, a quasinormal mode with frequency \( \lambda \) is supposed to be a solution of (8) where we require "outgoing" behavior at both ends of the physical
Since the differential operator in (3) would be self-adjoint acting on normalizable wavefunctions, and hence would have to have real eigenvalues, there are no quasinormal modes with $\text{Im} \lambda < 0$. So we take $\text{Im} \lambda > 0$, and then in (9), (10) we are asking for the exponentially decreasing component to be absent at both ends. It is actually quite delicate to define exactly what this means! If $V[r(x)]$ were strictly vanishing at $x = 1$ then one could just require that $e^{i \lambda x}$ be strictly proportional to $e^{i \lambda x}$ as appropriate, but for more generally $V[r(x)]$ we do not know any way of defining the boundary condition using only the behavior of $e^{i \lambda x}$ on the real line. This problem was also discussed in [19] where it was suggested that the appropriate condition would be obtained by finding an analytic extension of $e^{i \lambda x}$ to $\text{Im} \lambda < 0$ and demanding exponential decrease there; this was further shown to be equivalent to looking for poles in an appropriate Green's function. In [9] another criterion was given in terms of the coefficients of a power series representation for $e^{i \lambda x}$; this criterion is what was used in the analytical calculation of the asymptotic quasinormal frequencies in [14].

Here we wish to use another way of defining the boundary condition, by analytic continuation in $r$ instead of $x$. (The method we describe below has been studied before, e.g. in [21]; see also [15] for a recent discussion and additional references.) By considering complex $r$ we can easily define the boundary condition at the regular singular point $r = 1$, because the functions $e^{i \lambda x}$ are distinguished by their monodromy there. Namely, $e^{i \lambda x} = (r - 1)^{i \lambda} e^{i \lambda r}$, so to get $e^{i \lambda x}$ near $r = 1$ we simply require that $(r)$ have monodromy $e^{2 i \lambda}$ on a counterclockwise circle around $r = 1$. What is more subtle is to define the boundary condition at $r = 1$, but this can be done by analytically continuing $(r)$ via "Wick rotation" to the line $\text{Im} !x = 0$, where the asymptotic behavior of the solutions is purely oscillatory and hence one can really pick out a particular solution by specifying its asymptotics. In the limit where $!x$ is almost pure imaginary, the line $\text{Im} !x = 0$ is slightly tilted off the line $\text{Re} x = 0$. There are two possible directions for the Wick rotation and we choose the rotation through an angle smaller than $\pi/2$. For the time being we assume $\text{Re} !x > 0$; in this case $x = 1$ gets rotated to $!x = 1$, so our boundary condition $\lambda r = 1$ is actually

$$(r) \quad e^{i \lambda x} \text{ as } !x > 1 ; \quad (11)$$
2.4 Computation of quasinormal frequencies

Having defined the quasinormal modes we now proceed to study their frequencies, in the limit $\Im \lambda \to 0$. Indeed, until the end of this computation we will behave as if $\lambda$ were purely imaginary.

We will compute in two different ways the monodromy of $(r)$ around the contour shown in Figure 2, beginning and ending at the point marked $A$.

![Figure 2: Contour for the calculation of quasinormal frequencies, shown in terms of $r$ and in terms of $z = x + i$. The singularities at $r = 0$ (equivalently $z = 0$) and $r = 1$ (equivalently $z = 1$) are marked. The rotation by $3 = 2$ in the $r$ plane becomes a rotation by $3$ in the $z$ plane as follows from (12). The monodromy of $\log(r - 1)$ around $r = 1$ causes a 2 imaginary discontinuity in the path in the $z$-plane. The regions with $\Re x < 0$ are denoted by a darker color. The wave function is well approximated by a sum of Bessel functions in the blue circle around $r = 0$.](image)

It will prove convenient to use the coordinate $z = x + i$ instead of $x$. Actually, this definition is slightly in precise since we have not specified which branch of the logarithm in $x(r)$ we should choose. Depending on the branch, the contour in the $z$-plane will approach some point $z = 2$ in as $r$ approaches $0$; for convenience we choose the branch so that $n = 0$.

First we compute the monodromy by matching the asymptotics along the line $\Im \lambda \to 0$. Beginning at $A$, the plane wave behavior (11) can be extrapolated toward the interior since the term $\lambda^2$ dominates $V$ in (8) away from a small neighborhood around $r = 0$. As we extrapolate up from $A$ we reach $r = 0$ at $z = 0$, and near this point we have

$$z = r + \log(r - 1) + \frac{1}{2} r^2; \quad (12)$$
so in a neighborhood of \( r = 0 \) we may write

\[
V \left[ r(z) \right] \frac{j^2}{4 z^2} = 1
\]

Thus (3) may be simplified near \( r = 0 \) to

\[
\frac{\theta^2}{\theta z^2} + \frac{j^2}{4 z^2} \frac{1}{j^2} (z) = 0;
\]

This equation can be exactly solved in terms of Bessel functions; for generic \( j \), the general solution is

\[
(z) = A + c \sum_{j=0}^{\infty} \frac{P_{-j}^j}{z} J_{j+2}^j(|z|) + A c \sum_{j=0}^{\infty} \frac{P_{-j}^j}{z} J_{j+2}^j(|z|);
\]

We choose the normalization factors \( c, c' \) so that the asymptotics are

\[
c \sum_{j=0}^{\infty} \frac{P_{-j}^j}{z} J_{j+2}^j(|z|) \to 2 \cos(|z|) \quad \text{as} \quad |z| \to \infty;
\]

where we defined

\[
= \frac{1}{4} (1 - j);
\]

The phase shifts by \( \pi/2 \) will be very important for our analysis. Using (15) and (16) together with the boundary condition (11) which states that \( e^{i|z|} \) must be absent as \( |z| \to \infty \), we have

\[
A \sum_{j=0}^{\infty} \frac{P_{-j}^j}{z} e^{i|z|} + A \sum_{j=0}^{\infty} \frac{P_{-j}^j}{z} e^{i|z|} = 0;
\]

while for the coefficient of \( e^{i|z|} \) we have

\[
(z) \quad A \sum_{j=0}^{\infty} \frac{P_{-j}^j}{z} e^{i|z|} + A e^{i|z|} \quad \text{as} \quad |z| \to \infty;
\]

To follow the contour through to \( B \) we now have to turn through an angle \( 3\pi/2 \) around \( z = 0 \), or equivalently \( \pi/2 \) around \( z = 0 \). Using the fact that

\[
J_{j=2}^2(|z|) = \sum_{j=2}^{\infty} \frac{P_{-j}^j}{z} J_{j=2}^j(|z|);
\]

where \( J \) is an even holomorphic function of \( z \), after the rotation the asymptotics are

\[
c \sum_{j=2}^{\infty} \frac{P_{-j}^j}{z} e^{i|z|} \quad e^{i|z|} \quad 2 \cos(|z|) \quad \text{as} \quad |z| \to \infty;
\]

Then using (15), (21) we get the asymptotics at \( B \),

\[
(z) \quad A \sum_{j=0}^{\infty} \frac{P_{-j}^j}{z} e^{i|z|} + A e^{i|z|} + A \sum_{j=0}^{\infty} \frac{P_{-j}^j}{z} e^{i|z|} + A e^{i|z|} \quad \text{as} \quad |z| \to \infty
\]

as \( |z| \to \infty \). Finally, we can continue along the large semicircle in the right half-plane from \( B \) back to \( A \). Since we are in the region where \( |z| \leq 2 \),
dom inates the potential in (8) we essentially just have plane wave behavior; this approximation can be trusted at least for the coe cient of $e^{\text{j}3z}$, which therefore remains unchanged as we continue back to $A$ and complete the contour (however, the same cannot be said for the coe cient of $e^{\text{j}4z}$, which makes only an exponentially small contribution to $(z)$ in the right half-plane and hence can be modified by the small correction terms in the WKB approximation.) In the end we nd that the monodromy around the contour multiplies the coe cient of $e^{\text{j}3z}$ by a factor

$$
\frac{A_{+} e^{\text{j}1} + A e^{\text{j}2}}{A_{+} + A e^{\text{j}2}} = \frac{e^{\text{j}1} \frac{e^{\text{j}1}}{e^{\text{j}2}}}{e^{\text{j}2} \frac{e^{\text{j}2}}{e^{\text{j}1}}} = \frac{\sin 3}{\sin 2} = (1 + 2 \cos \text{j}) \quad (23)
$$

On the other hand, we can also obtain the monodromy action by observing that the only singularity of $(r)$ or $e^{\text{j}2z}$ inside the contour is at $r = 1$. By our boundary condition going around $r = 1$ clockwise just multiplies $(r)$ by $e^{\text{j}2}$, but it multiplies $e^{\text{j}3z}$ by $e^{\text{j}2}$, so the coe cient of $e^{\text{j}3z}$ in the asymptotics of $(r)$ must be multiplied by $e^{\text{j}2}$ after the full round trip. Comparing with (23) gives

$$
e^{\text{j}4} = (1 + 2 \cos \text{j}) \quad (24)
$$

Note that if we had chosen $\text{Re}! < 0$ we would have had to Wick rotate in the opposite direction, hence set our boundary conditions at $B$ instead of $A$, and run the contour in the opposite direction; hence we would have gotten (24) with $e^{\text{j}4}$ instead of $e^{\text{j}2}$. This is as expected since $!$ is a quasimonodal frequency then $!$ must also be one; the corresponding wave functions are simply complex conjugates of one another. The two possibilities can be summarized by the equation

$$
\exp \left( \text{Re}! \frac{4!}{4!} \right) = (1 + 2 \cos \text{j}) \quad (25)
$$

implying

$$
\text{j} \quad \text{Re}! = \text{log !} + 2 \cos \text{j} \quad (26)
$$

In the case $j = 0; 2$ we recover the numerical result of [9, 10, 11, 12] which was so important for [1, 13]:

$$
4! = (2n + 1) i \quad \text{log}(3) \quad (27)
$$

If our analysis of the dependence on $\text{Re}(!)$ is correct, it implies $\text{j} + 2 \cos \text{j} = 1$. Hence for $j = 2$ ($1=2; 3=2$) + $2Z$, there cannot be any asymptotic quasimonomodal modes, with the possible exception of the case $j = 2Z + 1$. This case is exceptional in our analysis for another reason as well: if $j = 1$, then
our form (13) for the leading singularity vanishes. A more careful analysis
would be desirable to check whether our results still hold in this case.)

We should mention that (25) is equivalent to a more complicated equation
derived in [14], namely
\[ \tan(i!) \tan(i! + j=2) \tan(i! - j=2) = i \text{ (Re!)} \] (28)
This equivalence can be shown by multiplying (28) by
\[ \cos(i!) \cos(i! + j=2) \cos(i! - j=2) \] (29)
and expressing the sines and cosines in terms of exponentials.

2.5 Some convenient notation

For later convenience we now describe the preceding computation in a more
compact notation. First write
\[ (m)_h = (A \cdot e^{im} + A \cdot e^{im}) \] (30)
and
\[ (m ; n)_h = (m)_h e^{-iz} + (n)_h e^{iz} \] (31)

Then the asymptotic matching through the Bessel region which we did by
comparing (16) and (21) shows that a 3 clockwise rotation in $z$ transforms the
asymptotic behavior by
\[ 3 : (m ; n)! (n + 6 ; m + 6); \] (32)
where the swap between $m$ and $n$ arises because of the swap $!z$ $5$ $!z$
needed to compare (16) and (21).

In the case of four-dimensional Schwarzschild we read off the initial
asymptotics from (16) as \((1; 1)_h\). Since the coefficient of $e^{ix}$ had
to vanish at $A$ we got the constraint
\[ (1)_h = 0; \] (33)
The 3 rotation (32) gave
\[ (1; 1)_h \rightarrow (5; 7)_h; \] (34)
so following the coefficient of $e^{ix}$ back around the semicircle gives its mon-
odromy as $(5)_h = (1)_h$, which we computed using the constraint (33), obtaining
\[ \frac{(5)_h}{(1)_h} = (1 + 2 \cos j); \] (35)
3 Quasinormal frequencies for other black holes

Having reproduced the result of [14] for \( d = 4 \) Schwarzschild, we now apply the same technology to two other classes of black hole. The generalizations are surprisingly straightforward.

3.1 Higher-dimensional Schwarzschild black holes

First we consider Schwarzschild black holes in arbitrary \( d \geq 4 \). We will verify a conjecture from [14]: namely, the asymptotic quasinormal frequencies of the Schwarzschild black hole with \( \text{Re} \lambda > 0 \) satisfy

\[
\text{e}^\lambda = 3 \quad (36)
\]

where \( \lambda \) is the Hawking temperature of the black hole. (Strictly speaking, we will prove this only for scalar perturbations and for certain tensor modes; we do not know the appropriate potentials for general perturbations in \( d > 4 \).)

To write the generalization of (3) to \( d \geq 4 \) we need the warp factor for \( d \)-dimensional Schwarzschild,

\[
g_{00} = f(r) = 1 - \frac{1}{r^d 3} ; \quad (37)
\]

where we again chose units in which the horizon is at \( r = 1 \). Then the perturbation satisfies

\[
f(r) \frac{\partial^2}{\partial r^2} \# + \text{V}(r) \lambda^2 (r) = 0 ; \quad (38)
\]

where \( \text{V}(r) \) is known for scalar perturbations to be [22]

\[
\text{V}(r) = f(r) \frac{1(d + 3)}{r^2} + \frac{(d - 2)(d - 4)f(r)}{4r^2} + \frac{(d - 2)f^2(r)}{2r} ; \quad (39)
\]

As in the \( d = 4 \) case, this \( \text{V}(r) \) grows large only at \( r = 0 \), and direct computation gives the coefficient of the singularity as

\[
\text{V}(r) \quad \frac{(d - 2)f}{4r^{2d} 4} ; \quad (40)
\]
Now we want to describe the tortoise coordinate in d spacetime dimensions. From the warp factor (37) we get the requirement

$$dz = 1 \frac{1}{r^{d-3}} \frac{1}{dr};$$

which can be integrated to give

$$z = r + \sum_{j=0}^{\infty} \frac{e^{2i\phi(d-3)}}{d-3} \log(1 + re^{2i\phi(d-3)})$$

where we chose the additive constant so that $z = 0$ for $r = 0$. From (42) we obtain the behavior of $Re z$ as shown in Figure 3. Unlike the situation in $d = 4$, (42) includes phases multiplying the logarithms which come from the "tortuous horizons" $r = e^{2i\phi(d-3)}$, so that $Re z$ is not well defined for arbitrary $r$; but so long as we stay in the right part of the $r$-plane it is well defined.

Near $r = 0$, $d$ terms in the Taylor expansion of (42) near $r = 0$ cancel and

$$z \sim \frac{r^d}{d} \frac{2}{2};$$

generalizing the behavior (12) in the $d = 4$ case. Actually, this cancellation can be seen directly from (41), by neglecting the term 1 on the right hand side.

Now we can express the singularity of the potential in terms of $z$; combining (40) and (43) we find simply

$$V[r(z)] = \frac{1}{4z^2};$$

Note that this is exactly the same as the behavior for scalar perturbations in $d = 4$; namely, it agrees with (13) at $j = 0$. The other case for which we know
the potential is a particular family of tensor metric perturbations studied in [23], which exist only in \( d > 4 \); for these the leading singularity corresponds again to \( j = 0 \). (One might have expected \( j = 2 \), but in our final result \( j \) appears only in \( \cos j \), so that \( j = 0 \) and \( j = 2 \) are indistinguishable.) We conjecture that with some suitable interpretation this form for the potential will actually persist for all \( j \), so that the 1 may be replaced by \( \frac{1}{2} \) in (44), but the skeptical reader may just set \( j = 0 \) in the rest of this section.

At any rate, writing the potential in this form, the Bessel function behavior of the solutions near \( r = 0 \), expressed in terms of \( z \), is just as it was in \( d = 4 \), and again we have plane wave behavior away from a neighborhood of \( r = 0 \). Furthermore, although the left part of the \( r \)-plane is rather complicated, the behavior of \( \Re \) on the right part is essentially unchanged from \( d = 4 \). So we can repeat the argument from the previous section. The calculation of the monodromy by matching asymptotics in the \( z \)-plane works exactly as in four dimensions, while the factor \( e^{i \pi} \) from the monodromy around \( r = 1 \) is modified to \( e^{i \pi} = (d - 3) \), because of the coefficient \( 1 = (d - 3) \) multiplying \( \log(1 - r) \) in (42).

Fortunately, this same factor appears in the formula for the Hawking temperature of a \( d \)-dimensional black hole. Namely, recall that the Hawking temperature can be computed as the surface gravity of the black hole:

\[
T_{\text{Hawking}} = \frac{\frac{\partial}{\partial \phi} f^0(\phi)}{4} = \frac{d}{4};
\]

(45)
giving \( \phi = (d - 3) \). Hence the monodromy of the coefficient \( e^{i \pi X} \) around the contour is \( e^{i \pi} \), and comparing this to the result from Bessel asymptotics gives

\[
e^{i \pi} = (1 + 2 \cos j);
\]

(46)
as desired.

In fact the agreement between the surface gravity and the coefficient of the logarithm in the tortoise coordinate is not a coincidence and holds more generally. This is because a horizon is characterized by the condition \( f(r_H) = 0 \), and the tortoise coordinate near \( r_H \) then obeys

\[
z = \frac{dz}{f(r)} = \frac{dr}{f(r) f^0(r_H)} = \frac{1}{f^0(r_H)} \log(r - r_H)
\]

(47)
while the surface gravity is \( f^0(r_H) = 4 \).

Our result implies that for scalar and some gravitational perturbations

\[
\Re ! = T_{\text{Hawking}} \log(3);
\]

(48)
In the revised version of [24], considerations of Bohr-Sommerfeld quantization (as originally proposed by Bekenstein and amplified e.g. in [25]) led to the conjecture that \( \text{Re} \! = \! \frac{2\pi}{\text{ln} k} \text{ln} (k) \) for some \( k \); our calculation establishes this conjecture and furthermore determines the integer \( k = 3 \).

3.2 Four-dimensional non-extremal Reissner-Nordstrom black holes

Finally we want to extend our results to non-extremal Reissner-Nordstrom black holes in \( d = 4 \). In this case the warp factor is

\[
f(r) = 1 + \frac{2GM}{r} + \frac{Q^2}{r^2} = \frac{(r - 1)(r - k)}{r^2}
\]

where we have fixed our units by setting \( GM = (1 + k) = 2, Q^2 = k \), so that the outer horizon is at \( r = 1 \) and the inner horizon is at \( r = k - 1 \). The tortoise coordinate is therefore determined by

\[
dz = dr \frac{r^2}{(r - 1)(r - k)};
\]

which integrates to

\[
z = r + \frac{\text{log}(1 - r)}{k} \text{log}(1 - r = k)
\]

where we have again fixed the constant so that \( z = 0 \) at \( r = 0 \). Then near \( r = 0 \) we end

\[
z = \frac{r^3}{3k};
\]

The form of the potential can be found in [29]: both for scalar perturbations and for axial-electron-axial-gravitational perturbations (which are coupled in this background, so we cannot talk about electromagnetic or gravitational perturbations separately) the potential is singular only near \( r = 0 \), and the leading singularity is

\[
V(r) = \frac{2k^2 r^6}{4\pi^2} \text{ scalar perturbation}
+ \frac{4k^2 r^6}{4\pi^2} \text{ electron axial-electro-gravitational perturbation}
\]

Using (52) we can rewrite this in the familiar form

\[
V(r(z)) = \frac{r^2}{4\pi^2} \text{ scalar perturbation}
+ \frac{r^2}{4\pi^2} \text{ electron axial-electro-gravitational perturbation}
\]
(with all the $k$ dependence disappearing) and, remarkably, the values of $j$ which come out are nice:

$$j = \begin{array}{c}
1 = 3 \text{ scalar perturbation} \\
5 = 3 \text{ electromagnetic-gravitational perturbation}
\end{array}$$

Figure 4: Regions with $\text{Re}(z) < 0$ (darker) in the $r$-plane for four-dimensional non-extremal Reissner-Nordstrom, with a contour for the calculation of quasinormal frequencies, shown both in the $r$-plane and the $z$-plane.

Hence the Bessel function behavior near $r = 0$ will be unchanged from the previous examples, and our calculation will proceed in an almost identical manner. However, in this case we must use a slightly more complicated contour, going around a "lobe" as shown in Figure 4; the point is that we want to capture only the outer horizon at $r = 1$, where we know the boundary conditions and hence know the monodromy, and avoid the inner horizon at $r = k$. As a result, this computation is only valid in the non-extremal case $k < 1$.

The corresponding picture in the $z$-plane looks rather complicated because a given $z$ may or may not lie in a "Bessel region" depending on whether or not the $r$-plane contour is passing near $r = 0$ (the potential is a multi-valued function of $z$ but an ordinary function of $r$.) In Figure 4 this is indicated by letting the contour pass over or under the blue circles when $z$ is not passing through a Bessel region; it is easiest to understand that figure by redrawing it yourself, following the given $r$-plane contour starting at $A$ and tracing out the corresponding $z$-plane behavior.

The matching of asymptotic expansions in this case can be done following the recipe given in Section 2.5. As before, we begin at the point marked $A$...
with the asymptotic behavior \( (1; 1) \), and we have the boundary condition
\[
(1)_{A} = 0 \quad (56)
\]
Going through a 2 rotation in \( z \) gives (compare (32))
\[
2 : (m; n)! (m + 4; n + 4) \quad (57)
\]
which is in this case \( (1; 1)_A \) ! \( (5; 3)_A \). Then we can go out along the lobe where in our approximation the behavior is purely oscillatory. After going around the lobe we have to return to the Bessel region a second time. However, the asymptotics in terms of \( z \) will be different this time: we chose the branch of \( z \) so that the first time we entered the Bessel region it was at \( z = 0 \), but now we have traveled an additional distance in \( z \) (from changing branches of the second logarithm in (51)), namely
\[
= 2 i^k (1 k) \quad (58)
\]
So we may write the solution as
\[
(z) = B, c, P \left( \frac{1}{(z)} \right) J_{j=2}(! (z)) + B, c, P \left( \frac{1}{(z)} \right) J_{j=2}(! (z)) \quad (59)
\]
Introducing a slight modification of our previous notation, we write
\[
(n) = e^{i\pi/2} (n) \quad (60)
\]
Then from (59) we obtain \( (1; 1)_B \), giving the constraint
\[
(5; 3)_B = (1; 1)_B \quad (61)
\]
Making the second 2 rotation we get \( (1; 1)_B \) ! \( (3; 5)_B \), so the asymptotics near the point \( B \) are \( (3; 5)_B \). Now running over the big semicircle to get back to the point \( A \), as before, the WKB approximation allows us to claim the coefficient of the exponentially big component \( e^{\pm i\pi/2} \) is unchanged. So over the full round trip this component is multiplied by \( 3 \) \( (3) = (1) \). Between (56) and (61) we have three homogeneous linear constraints on the four coefficients \( A \), \( B \), so we can determine this ratio; it turns out to be
\[
\frac{(3)}{(1)} = (1 + 2 \cos j) \quad e^{2i\pi} (2 + 2 \cos j) \quad (62)
\]
The contour encloses only the singularity at \( r = 1 \) (the outer horizon), so the monodromy comes only from the multivaluedness of \( e^{i\pi/2} \) around \( r = 1 \). As discussed in the previous section, this monodromy is determined by the surface gravity of the horizon at \( r = 1 \), namely
\[
= \frac{4}{f^0(1)} = \frac{4}{1} k \quad (63)
\]
Also note that \( 2i = k^2 \). Then matching the monodromies we obtain the nal result,

\[
e^j = (1 + 2 \cos j) \quad e^k (2 + 2 \cos j) : (64)
\]

The rst term looks exactly like the result (36) from Schwarzschild, and then there is a correction term which came from the phase shift. Actually, this term can also be written in terms of a Hawking temperature, but this time the Hawking temperature of the inner horizon:

\[
r = \frac{4}{f_0(k)} = \frac{4k^2}{k} = k^2 : (65)
\]

At any rate, substituting \( j = 1=3 \) or \( j = 5=3 \), from (55), gives the same answer in each case:

\[
e^j = 2(3k^2) : (66)
\]

So this is our result for the asymptotic quasinormal frequencies of scalar or axial electromagnetic-gravitational perturbations of Reissner-Nordström in \( d = 4 \). This result suggests a somewhat more complicated asymptotic behavior for the quasinormal frequencies than we found in the case of Schwarzschild; in particular, the asymptotic frequencies seem to be aperiodic unless \( k^2 \) is rational, and the real parts do not settle down to a simple value.

We note that by taking \( k \) slightly imaginary it would be possible to get rid of the last term in the asymptotic limit, and in this case one would obtain asymptotically \( \text{Re} ! = T_{\text{Hawking}} \log(2) \). This may not be an unreasonable thing to do, since \( k \) is related to the charge and mass of the black hole, and the mass should be considered as slightly imaginary (the black hole eventually evaporates.) Indeed, if \( Q \) is real and \( \neq 0 \), then \( M \) is a decreasing function of \( k \), so the expected small negative imaginary part of \( M \) corresponds to a small positive imaginary part of \( k \), which is the correct sign to suppress the last term. Following [1, 13] and identifying this \( T_{\text{Hawking}} \log(2) \) with a quantum of energy emitted by a black hole, we note that this corresponds precisely to the black hole reducing its outer horizon area by \( 4G \log(2) \) while keeping \( Q \) fixed.

One might be concerned that our result for Reissner-Nordström is incompatible with the known results for Schwarzschild because it does not reduce to \( T_{\text{Hawking}} \log(3) \) as \( k \to 0 \). There is no inconsistency; rather, there is an order-of-limits issue. For extremely small \( k \), \( \text{Re} ! \) will be approximately \( T_{\text{Hawking}} \log(3) \) for a large range of \( \text{Im} ! \) but then eventually switch over to the Reissner-Nordström behavior determined by (66); the value of \( \text{Im} ! \) at which the crossover occurs goes to 1 as \( k \to 0 \). We can make a rough estimate of the critical value \( k = k_0 \) above which the Reissner-Nordström...
description becomes more appropriate than the Schwarzschild description; namely, it is the point where the leading term \( k^2 - r^6 \) is of the same order as the term \( 1 - r^4 \) which would be leading for the Schwarzschild black hole. To compare these two terms the relevant \( r \) is the place where we patch the plane wave with the Bessel function solution, namely \( z = 1 \). To relate \( z \) to \( r \) we can use either the relation \( z = r^2 \) from Schwarzschild or \( z = r^2 - k \) from Reissner-Nordström. With either choice, requiring \( k^2 - r^6 = 1 - r^4 \), i.e. \( k = r \), we obtain finally \( k r = 1 = 2 \) i.e.

\[ k_0(1!) \quad 1 = 2 \]  

(67)

If \( k = k_0(1!) \), the asymptotic Reissner-Nordström formula (66) is appropriate; if \( k \neq k_0(1!) \) the Schwarzschild result is appropriate.

After the preprint version of this paper appeared, the formula (66) as well as the order-of-limit its issue discussed above were confirmed explicitly in the numerical analysis of [26] (see also [27] for some discussion.)

4 Directions for further study

This work suggests various possible directions for further study:

The machinery developed here may be applicable more generally, e.g. to charged black holes in \( d > 4 \), and perhaps even to general rotating black holes. Some work in this direction is in progress for the Kerr black hole in \( d = 4 \) [28]. In addition one could consider the case of black holes in de Sitter or anti-de Sitter space; quasinormal frequencies in these backgrounds have recently been studied [29, 30], and recently some exact results have been obtained in the limit where the Schwarzschild horizon nearly coincides with the de Sitter horizon [31]. The asymptotic quasinormal frequencies in these backgrounds are related to properties of the holographic dual theory [32, 33]. The method will however require some modification, since the potential no longer vanishes at infinity, and the expected answer is quite different (the real part is expected to diverge along with the imaginary part [29, 32].)

Our results so far only give the asymptotic real part of the frequency in the limit of finite imaginary part. It may be possible to extend the technique to obtain a systematic expansion including corrections in \( 1 - \frac{1}{j^2} \). After the preprint version of this paper appeared, the \( j \) and \( l \) dependence of the first correction for arbitrary \( j \) appeared in
and the exact correction for $j = 2$ including numerical coefficient was computed in [34].

It would be desirable to have some numerical calculations of the asymptotic quasinormal frequencies in the cases we considered above, to confirm or reject our proposed analytic solution. In the case of Reissner-Nordström, after the preprint version of this paper appeared, such calculations were indeed done [26] and confirmed our solution in detail (the agreement is also discussed in [27]). However, the case of higher-dimensional black holes remains numerically unstudied as far as we know.

In $d > 4$ Schwarzschild we could only give results for certain types of perturbation, because so far a good theory of more general perturbations in these dimensions is apparently lacking. It would be nice to understand how the leading term in the potential depends on the type of perturbation.

According to our calculation, the asymptotic real part of the frequency depends only on the coefficient of the leading term in the potential. This leading term becomes important only near the singularity at $r = 0$, but it still affects the transmission amplitude in the physical region between the horizon and infinity. Although the importance of the singularity at $r = 0$ was purely mathematical in our approach, there could be a more physical explanation of why our procedure works. Can we view it as a manifestation of the complementarity principle, reflecting some kind of duality between what happens inside and outside the horizon?

The occurrence of the Hawking temperature for the inner horizon of the Reissner-Nordström black hole is surprising. How can the quasinormal modes know about the behavior of the black hole in the causally disconnected interior?

The original motivation for this work was the LQG explanation [1] of the $\log(3)$ in $d = 4$ Schwarzschild in terms of a spin network with links of spin 1. If LQG is correct, perhaps the more complicated behavior for Reissner-Nordström should have a similar explanation. The possible appearance of $\log(2)$ in the asymptotic frequencies could support some recent claims [35] that the gauge group of LQG should be SU(2) despite the $\log(3)$ for Schwarzschild.

Similarly, can spin foam models or other models explain the fact that the $\log(3)$ for Schwarzschild black holes seems to be independent of dimension?
We have answered some questions about the asymptotic quasinormal frequencies of black holes, but many more remain open.

Acknowledgments

We are grateful to N. Arkani-Hamed, V. Cardoso, K. Kokkotas, K. Krasnov, A. Malone, M. Schnabl, and A. Strominger for useful discussions, and to A. Malone for reading a draft of this paper. The work of LM was supported in part by Harvard DOE grant DE-FG 01-91ER40654 and the Harvard Society of Fellows. The work of AN was supported by an NDSEG Graduate Fellowship.
