We report the results of a search for a charged Higgs boson in the decays of top quarks produced in \( p\bar{p} \) collisions at a center-of-mass energy of 1.96 TeV. We use a data sample corresponding to an integrated luminosity of 193 pb\(^{-1}\) collected by the upgraded Collider Detector at Fermilab. No evidence for charged Higgs production is found, allowing 95% C.L. upper limits to be placed on \( BR(t \rightarrow H^\pm b) \) for different charged Higgs decay scenarios. In addition, we present in the MSSM \( (m_{H^\pm}, \tan \beta) \) plane the first exclusion regions with radiative and Yukawa coupling corrections.

One of the open questions in the standard model (SM) of particle physics involves the mechanism of electroweak symmetry breaking (EWSB). Within the SM it is postulated that a single scalar doublet field breaks the symmetry, resulting in a single observable particle of unknown mass called the Higgs boson \( H^0 \). To date, the SM Higgs boson has not been observed, and extensions of the SM have been proposed with different Higgs phenomenologies. The simplest extension of the SM Higgs sector introduces another Higgs doublet. In two-Higgs doublet models EWSB results in five Higgs bosons, three of which are neutral \( (h^0, H^0, A^0) \) and two of which are charged \( (H^\pm) \). The minimal supersymmetric extension of the SM (MSSM) includes a two-Higgs doublet sector.
in which one doublet couples to the up-type quarks and neutrinos, and the other to the down-type quarks and charged leptons. The observation of a charged Higgs boson would provide unambiguous evidence of a Higgs sector richer than that predicted by the SM.

At the Tevatron, direct production of single charged Higgs is expected to be negligible, and the direct production of $H^+H^-$ via the weak interaction is expected to have a relatively small cross section on the order of 0.1 pb. The production of $t\bar{t}$ pairs, with a theoretical production cross section of $6.7^{+0.9}_{-0.7}$ pb for $m_t = 175$ GeV/c$^2$, may offer another source of charged Higgs production. If kinematically allowed, the top quark can decay to $H^+b$, competing with the SM decay $t \to W^+b$. This mechanism can provide a larger production rate of charged Higgs and offers a much cleaner signature than that of direct production.

Previous searches for the charged Higgs boson have been performed at $\sqrt{s} = 1.8$ TeV in the $\tau_\ell + E_T + \ell$ channels, where the missing energy $E_T$ is defined in $\ell$, $\tau_\ell$ denotes a tau lepton which decays to hadrons, and where $\ell = e$ or $\mu$ in $\ell$ and $\ell = e, \mu$ or $\tau_\ell$ in $\tau_\ell$. In the framework of the tauonic Higgs model, in which the charged Higgs decays exclusively to $\bar{\ell}v$, these searches set limits directly on BR$(\tau_\ell \to H^+b)$ based on the measured production rate. These results are then translated into limits on $\frac{\beta}{\alpha}$, the ratio of vacuum expectation values of the two Higgs doublets. Other searches obtained limits in the $(m_{H^\pm}, \tan \beta)$ plane, assuming that the charged Higgs decays only to $\bar{\tau}\nu$, $c\bar{s}$, and $t^*b$ ($W^+b\bar{b}$) in the $E_T + \ell$ channel with $\ell = e$ or $\mu$ in $\ell$, where $t^*$ is a virtual top quark.

These limits utilize tree-level MSSM predictions of the $t \to H^+b$ and charged Higgs branching fraction as a function of tan $\beta$. It is now known that higher-order radiative corrections significantly modify these predictions. The corrections strongly depend on the parameters of the model and are particularly large at high values of tan $\beta$. In addition, it is also predicted that in the low tan $\beta$ region, the charged Higgs has a sizable branching fraction to $W^+h^0$.

CDF has recently reported measurements of the $t\bar{t}$ production cross section in the $E_T + \ell + X$ channels, where $\ell = e, \mu$ and $X = \ell$ (the “dilepton” channel), $X = \tau_\ell$ ("lepton+tau"). $X$ = one or more tagged jets [12] ("lepton+jets, $\geq 1$ tag"), and $X$ = two or more tagged jets ("lepton+jets, $\geq 2$ tags"). These measurements are carried out under the assumption BR$(t \to H^+b) = 0$ and use data samples corresponding to an integrated luminosity of up to 193 pb$^{-1}$. Each measurement agrees with the SM $t\bar{t}$ cross section expectation within its uncertainty, providing no evidence for non-SM physics. In this analysis, we consider the possibility of $t \to H^+b$ and recast the cross section results to set limits on charged Higgs production. Depending on the top and Higgs branching ratios, the number of expected events in these decay channels can show an excess or deficit with respect to SM expectations.

Table I: Number of events in each exclusive channel from non-t$t$ SM background sources, observed in data, and total expected assuming $\sigma_{t\bar{t}}^{prod} = 6.7$ pb and $BR(t \to H^+b) = 0$.

As published, these measurements allow the categorization of a single event in multiple channels. In this analysis extra requirements are applied to each channel in order to force the association of every event to a single channel. The $t\bar{t}$ signal acceptance and non-$t\bar{t}$ SM background contribution to each of these exclusive channels are recalculated, and the changes from the original cross section analyses are found to be mostly negligible. The only exception to this is the “$\geq 1$ tag” and “$\geq 2$ tags” lepton+jets channels, where the latter is a proper subset of the former. Removal of this 100% overlap changes the “$\geq 1$ tag” channel to exactly one tag, $n^\tau = 1$ tag”. The results for these new exclusive channels in terms of background, number of observed events, and number of SM expected events are shown in Table II. We assume that the charged Higgs boson can decay only to $\bar{\tau}\nu$, $c\bar{s}$, $t^*b$ or $W^+h^0$, leading to five possible decay modes for a single top quark: (1) $t \to W^+b$, (2) $t \to H^+b$, $H^+ \to \bar{\tau}\nu$, (3) $t \to H^+b$, $H^+ \to c\bar{s}$, (4) $t \to H^+b$, $H^+ \to t^*b$, and (5) $t \to H^+b$, $H^+ \to W^+h^0$, $h^0 \to b\bar{b}$. Charge conjugated decays are implied. Allowing for a non-zero BR$(t \to H^+b)$, the acceptance of the detector for a given $t\bar{t}$ channel $k$ is

$$A_k = \sum_{i,j=1}^{5} B_i \cdot B_j \cdot \epsilon_{ij,k}(\Gamma_i, \Gamma_{H^\pm}, m_{H^\pm}, m_{h^0}),$$

where $B_i$ ($B_j$) represent the branching fractions of the top quark (anti-quark) to decay via mode $i$ ($j$) as listed above, and $\epsilon_{ij,k}$ is the efficiency to detect a $t\bar{t}$ event whose top quarks decay via modes $i$ and $j$ in channel $k$.

The efficiencies $\epsilon_{ij,k}$ are obtained from Monte Carlo (MC) simulation of $t\bar{t}$ events generated with different masses of the top, $H^\pm$, and $h^0$. The MC generator PYTHIA is modified to include the decay $H^+ \to t^*b$ and is used for the simulation of the $t\bar{t}$ events. The detector simulation and reconstruction algorithms for muons, electrons, and jets are identical to those used in the SM $t\bar{t}$ cross section measurements for the four channels. MC
eficiencies are scaled for known differences between MC simulation of the detector response and that observed in data. The dependence of the efficiencies on the width of the top quark ($\Gamma_t$) and the width of the charged Higgs ($\Gamma_{H^\pm}$) is taken into account using the simulated $t\bar{t}$ events. The systematic uncertainties on $\epsilon_{k,i}$ for the process $t\bar{t} \rightarrow W^+ b W^- \bar{b}$ are listed in Table [13, 14, 15] and do not differ much for the other possible decay modes.

The expected number of events in channel $k$ is

$$\mu_k = \sigma_{t\bar{t}}^{\text{prod}} \cdot A_k(\rho) \cdot L_k + n_k^{\text{back}},$$

where $\sigma_{t\bar{t}}^{\text{prod}}$ is the $t\bar{t}$ production cross section and $\rho$ represents a generic model from which the nine quantities (five BR’s, $\Gamma_t$, $\Gamma_{H^\pm}$, $m_{H^\pm}$ and $m_{\tilde{b}^0}$), needed to calculate the acceptance $A_k$, can be derived. $L_k$ is the integrated luminosity, and $n_k^{\text{back}}$ is the number of expected background events in channel $k$ (shown in Table [10]). We assume the inclusion of the Higgs sector does not modify the value of the $t\bar{t}$ production cross section and set it to $\sigma_{t\bar{t}}^{\text{prod}} = 6.7 \pm 0.9$ pb.

For each channel a likelihood is constructed based on the Poisson probability to observe $N_k$ events when a given model predicts $\mu_k$ events. Since the four channels were constructed to be mutually exclusive, the product of their likelihoods is taken to form a final likelihood. The posterior probability is integrated over its maximum density region for the four channels when the number of observed events is equal to that expected from the SM.

In the MSSM the nine quantities needed to calculate the acceptance are predicted from a specific set of MSSM parameters, including $m_{H^\pm}$ and $\tan \beta$. We use the computational package CPsuperH [17] to compute all the Higgs masses and branching ratios. This program includes QCD, SUSY-QCD, and SUSY-EW radiative corrections up to the two-loop leading logarithms and applies these corrections to the top and bottom Yukawa couplings. The top branching ratio to charged Higgs is computed with the same level of accuracy from custom code developed in collaboration with the authors of [11]. In the context of the MSSM with $m_{A^0} < m_{H^\pm}$, CPsuperH predicts that the $H^+$ decay to $W^+ A^0$ is non-negligible for masses of $H^+$ below 100 GeV/$c^2$. In this case CPsuperH also predicts the mass of the $A^0$ to be similar to that of the $h^0$, and we assume the kinematics of the decay to $W^+ A^0$ to be identical to that of $W^+ h^0$ when the $h^0$ and $A^0$ masses are equal. Thus, we assign to the decay $H^+ \rightarrow W^+ h^0$ a branching ratio of BR($H^+ \rightarrow W^+ h^0$) + BR($H^+ \rightarrow W^+ A^0$), effectively considering both decays.

As an example of how a charged Higgs alters the balance between the top decay channels, Fig. [10(a)] shows the expected number of events in each of the exclusive channels as a function of $\tan \beta$ for $m_{H^\pm} = 120$ GeV/$c^2$. The other relevant MSSM parameters are detailed in the caption. The figure demonstrates the excess expected in the lepton+tau channel and the deficit expected in the other channels for large $\tan \beta$ values. For values of $\tan \beta$ around 7 the BR($t \rightarrow H^+ b$) goes to zero and the SM expectation for the different channels is recovered. The relationship between the channels changes with charged Higgs mass. Values of $\tan \beta$ which result in a non-self-consistent Higgs sector are reported by CPsuperH and are shown as the theoretically inaccessible regions in Fig. [10].

Figure [10(b)] shows the posterior probability obtained for the four channels when the number of observed events is equal to that expected from the SM. The posterior is obtained by means of a flat prior in $\log_{10}(\tan \beta)$. This prior allows for a smooth variation of the top and charged Higgs branching ratios as a function of $\log_{10}(\tan \beta)$. The probability is integrated over its maximum density region to obtain expected upper and lower limits on $\tan \beta$ at the 95% confidence level (C.L.)
Using the number of events observed in the data and repeating this procedure for different Higgs masses results in the exclusion region shown in Fig. 2. We determine this exclusion region for several sets of benchmark parameters, including the maximal and minimal light Higgs mass scenarios described in [24]. The complete characterization of these scenarios and their results are described in [21]. In all the benchmarks used, the low tan β region is excluded in a similar region as shown in Fig. 2. The high tan β exclusion region, however, can be significantly reduced and even vanishes, due to parameters of particular benchmarks that suppress BR(t → H+b). The obtained exclusion limits strongly depend on the prior probability used. Using a flat prior in tan β, which is characterized by sudden changes in the top and charged Higgs branching ratios, yields significantly different exclusion regions. It is important to note that even if all the corrections were turned off, and tree-level calculations were used, the results would be significantly stronger than those obtained in [10] under the same conditions.

In the high tan β region the decay $H^+ → τν$ is expected to dominate in a large fraction of the MSSM parameter space. In this region the taunonic Higgs model is a good approximation, and we explicitly set BR($H^+ → τν$) = 1 and evaluate the posterior probability as a function of BR(t → H+b). The value of $Γ_{H^±}$ has little effect on the results as width corrections to the efficiency are small; we set $Γ_{H^±} = 1.4$ GeV/c². The width of the top is set to $Γ_t = 1.4$ GeV/c², and the value of $m_{H^0}$ is irrelevant in this model. We perform the scan in BR(t → H+b) from 0 to 1. A posterior probability density of BR(t → H+b) is obtained using a flat prior that is constant between 0 and 1 and null elsewhere. The 95% C.L. is obtained by integrating the posterior over the maximum density region. This procedure is repeated for different charged Higgs masses. In the region $80$ GeV/c² ≤ $m_{H^±}$ ≤ $160$ GeV/c² we exclude $BR(t → H^+ b) > 0.4$ at 95% C.L.

Finally, in order to reduce the model dependence, we place limits on BR(t → H+b) that hold for any combination of charged Higgs branching ratios. For a specific charged Higgs mass we divide each of the five charged Higgs branching ratios into 21 bins. This results in $1771$ possible branching ratio combinations subject to the relation $\sum_i BR(H^+ → X_i) = 1$. For each combination, we obtain a limit on BR(t → H+b) assuming BR($h^0 → bb$) = 0.9 and $m_{h^0} = 70$ GeV/c². The least restrictive limit is quoted and the analysis is repeated for different charged Higgs masses. The results are shown in Fig. 3. For $BR(t → H^+ b) > 0.9$ (hatched region) the width of the top is larger than $14$ GeV/c² and the analytical corrections to the efficiencies start losing accuracy.

In summary, we have performed a search for a charged Higgs boson in top quark decays using measurements of the top pair production cross section in four different final states and we find no evidence of signal in the region $80$ GeV/c² ≤ $m_{H^±}$ ≤ $160$ GeV/c². In the context of the MSSM with full radiative corrections we exclude the low tan β region for all benchmarks in [21]. The high tan β region cannot be excluded independent of the MSSM parameters. In the taunonic Higgs model, in which the charged Higgs decays exclusively to $τν$, the BR(t → H+b) is constrained to be less than 0.4 at 95% C.L. If no assumption is made on the charged Higgs decay, the BR(t → H+b) is constrained to be less than 0.91 at 95% C.L.

FIG. 3: Results for the charged Higgs branching ratio independent analysis with $m_t = 175 \text{ GeV}/c^2$. The dark solid region represents the CDF Run II excluded region in the $(m_{H^\pm}, \text{BR}(t \to H^+b))$ plane. The expected exclusion limits are indicated by a black solid line and the ±1σ confidence band around it is obtained by generating pseudo-experiments. The hatched region of $\text{BR}(t \to H^+b) > 0.9$ indicates that the width of the top is larger than 14 GeV/$c^2$.

[6] We use a cylindrical coordinate system about the beam axis in which $\theta$ is the polar angle. We define transverse momentum $p_T = p \sin \theta$ and transverse energy $E_T$ similarly. Missing transverse energy ($\bar{E}_T$) is defined as $-\sum_i E_i \mathbf{n}_i$, where $n_i$ is the unit vector in the azimuthal plane that points from the $p\bar{p}$ interaction region to the $i^{th}$ calorimeter tower. $\bar{E}_T$ is further corrected for the energy and momentum of identified muons.
[12] A jet is determined to be tagged if it shows a displaced secondary vertex. These jets typically originate from the decay of long lived mesons such as those resulting after the hadronization process of the b quark.
