Measurement of the $t\bar{t}$ Production Cross Section in $pp$ Collisions at $\sqrt{s} = 1.96$ TeV using Missing $E_T$+jets Events with Secondary Vertex $b$-Tagging

We present a measurement of the $t\bar{t}$ production cross section in $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV which uses events with an inclusive signature of significant missing transverse energy and jets. This is the first measurement which makes no explicit lepton identification requirements, so that sensitivity to $W \to \tau \nu$ decays is maintained. Heavy flavor jets from top quark decay are identified with a secondary vertex tagging algorithm. From 311 pb$^{-1}$ of data collected by the Collider Detector at Fermilab we measure a production cross section of $5.88^{+0.9}_{-0.7}$ (syst.) pb for a top quark mass of 178 GeV/$c^2$, in agreement with previous determinations and standard model predictions.

PACS numbers: 13.85.Ni, 14.65.Ha

At the Tevatron $p\bar{p}$ collider top quarks are produced mainly in pairs through quark-antiquark annihilation and gluon-gluon fusion processes. In the standard model (SM) the calculated cross section for pair production is $6.1^{+0.8}_{-0.6}$ pb $^1$ for a top mass of 178 GeV/$c^2$ $^2$, and varies linearly with a slope of $−0.2$ pb/GeV/$c^2$ with the top quark mass in the range 170 GeV/$c^2 < m_t < 190$ GeV/$c^2$. Because the Cabibbo-Kobayashi-Maskawa matrix element $V_{ub}$ is close to unity and $m_t$ is large, the SM top quark decays to a $W$ boson and a $b$ quark almost 100% of the time. The final state of top quark pair production thus includes two $W$ bosons and two $b$-quark jets.
When only one $W$ decays leptonically, the $t\bar{t}$ event typically contains a charged lepton, missing transverse energy from the undetected neutrino, and four high transverse energy jets, two of which originate from $b$ quarks. Previous cross section analyses select this distinct $t\bar{t}$ signature by requiring well-identified leptons ($e, \mu$) with high transverse momentum. In this Letter we describe a $t\bar{t}$ production cross section measurement which is sensitive to leptonic $W$ decays regardless of the lepton type, and has a sizable acceptance to $\tau$ decays of the $W$ boson. The direct identification of $\tau$ from $W \rightarrow \tau \nu$ decays suffers from a very low efficiency, thus our measurement, using data collected by a multijet trigger, selects top decays by inclusively requiring a high-$p_T$ neutrino signature rather than charged lepton identification. Events with well-identified high-$p_T$ electrons or muons are explicitly vetoed in order to avoid statistical overlap and provide complementary results with respect to lepton-based measurements.

Results reported in this Letter are obtained from 311 pb$^{-1}$ of data from $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV recorded by the Collider Detector at Fermilab (CDF II). The CDF II detector has been described in detail elsewhere. It consists of a magnetic spectrometer surrounded by calorimeter systems and muon chambers. The momenta of charged particles are measured up to a pseudorapidity range $|\eta| = 1.0$ in the central tracking chamber, which is inside a 1.4 T superconducting solenoidal magnet. Microstrip silicon vertex detectors, located immediately outside the beampipe, provide precise track reconstruction useful for vertexing and extend the $|\eta|$ coverage of the tracking system up to $|\eta| = 2.0$. Electromagnetic and hadronic sampling calorimeters, arranged in a projective-tower geometry, surround the tracking systems and measure the energy and direction of electrons, photons, and jets, providing good hermeticity in the pseudorapidity range $|\eta| < 3.6$. In addition, the calorimeter system allows the detection of high-$p_T$ neutrinos by the measurement of the missing transverse energy, $E_T$. Muon systems reside outside the calorimeters and consist of layers of drift chambers which allow the reconstruction of track segments for penetrating particles. The beam luminosity is determined using gas Cherenkov counters (CLC) located in the region $3.7 < |\eta| < 4.7$ which measure the average number of inelastic $p\bar{p}$ collisions per bunch crossing. The uncertainty on the luminosity measurement, due to CLC acceptance and theoretical uncertainties on the total inelastic $p\bar{p}$ cross section, is 6%.

The data sample used in this analysis is collected by a multijet trigger which requires four or more $E_T \geq 15$ GeV clusters of contiguous calorimeter towers, and a total transverse energy clustered in the calorimeter of $\sum E_T \geq 125$ GeV. The initial data sample consists of 4.2 million events. The understanding of signal acceptances and efficiencies relies on a detailed simulation of the production processes and the detector response. Inclusively decaying $t\bar{t}$ events, assuming a top quark mass of 178 GeV/$c^2$, are simulated using PYTHIA v6.2 and HERWIG v6.5 generators in conjunction with the CTEQ5L parton distribution functions, QQv9.1 for the modeling of $b$ and $c$ hadron decays, and a full simulation of the CDF II detector. Jets are identified as groups of calorimeter tower energy deposits which fall within a cone of radius $\Delta R = \sqrt{(\Delta\phi)^2 + (\Delta\eta)^2} \leq 0.4$. Jet energies, after the absolute energy scale setting, are corrected for calorimeter non-linearity, losses in the gap between towers, and multiple interactions.

The $t\bar{t}$ signature used in the present study ($E_T+$jets) consists of large missing transverse energy, $E_T$, associated with the neutrino from the leptonic decay of a $W$ boson, and jets. Since the $E_T$ resolution, $\sigma(E_T)$, is observed to degrade as a function of the total transverse energy of the event, in the form $\sigma(E_T) \propto \sqrt{\sum E_T}$, the missing $E_T$ significance, defined by $E_{T,\text{sig}} = |E_T|/\sqrt{\sum E_T}$, is used for event selection. Besides the requirement of large $E_{T,\text{sig}}$, further background rejection can be achieved by exploiting $E_T$-related geometrical properties. The neutrino direction for $t\bar{t} \rightarrow E_T + \text{jets}$ events is in general uncorrelated with the jet directions in the transverse plane. On the contrary, background events for which the $E_T$ is mainly due to jet energy mis-measurement or to $b$-quark semileptonic decays are more likely to have $E_T$ aligned with a jet direction. The minimum $\Delta\phi$ difference between the $E_T$- and any jet in the event, min $\Delta\phi(E_T, \text{jets})$, is used as an analysis cut. Events containing identified high-$p_T$ electrons or muons, as defined in $E_T$, are removed, in order to increase the relative contribution of $W \rightarrow \tau \nu$ decays and to provide a statistically independent sample with respect to other lepton+jets cross section analyses.

To reject events with only light quark or gluon jets, we require at least one jet to be identified as originating from a $b$-quark. The presence of $b$-jets (“tags”) is established by the identification of secondary decay vertices using the secvtx algorithm. An optimization procedure, aimed at minimizing the relative statistical uncertainty on the cross section measurement, sets $N_{\text{jet}}(E_T \geq 15 \text{ GeV}; |\eta| \leq 2.0) \geq 4$, $E_{T,\text{tag}} \geq 4.0$ GeV $1/2$, and min $\Delta\phi(E_T, \text{jets}) \geq 0.4$ rad as the best kinematical selection cuts. After these requirements the data sample is reduced to 597 events with an expected pre-tag signal to background ratio $S/B \sim 1/5$.

Background events with $b$-tags arise from QCD heavy flavor production, electroweak production of $W$ bosons associated with heavy flavor jets, and from false identification by the secvtx algorithm. The overall number of background $b$-tags is estimated from the multijet sample by applying a parametrization of the per-jet tagging probability. The tagging probability is calculated using $\sim 879,000$ multijet data events with exactly three jets.
having $E_T \geq 15$ GeV and $|\eta| \leq 2.0$. It is parametrized on a per-jet basis as a function of the jet $E_T$, track multiplicity, and the projection of the $\vec{E}_T$ along the jet direction, defined by $E_T^{prj} = \vec{E}_T \cdot \cos \Delta \phi (E_T, \text{jet})$. The $t\bar{t}$ contamination in this control sample is negligible. The jet $b$-tagging rate, calculated as the ratio of the number of $b$-tagged jets to the number of jets with at least two good tracks with hits in the silicon detector, is shown in Fig. 1.

The $E_T^{prj}$ parametrization accounts for background $b$-tags from $bb$ production processes, whose $b$-tag rate is enhanced at high positive values of the $E_T^{prj}$ due to the correlation of $E_T$ and $b$-jet direction in the case of a semileptonic quark decay. The extrapolation of the $3$-jet $b$-tag rate to higher jet multiplicity events is checked by comparing the predicted and observed $b$-tag rates as a function of the number of jets in the multijet sample without the kinematical selection on $E_T^\text{sig}$ and $\min \Delta \phi (E_T, \text{jets})$, as shown in Fig. 2(a). The capability of the parametrization to track possible sample composition changes introduced by the kinematical selection is established by constructing the ratio of observed over expected $b$-tags in two separate control samples of multijet data, depleted of signal contaminations, as shown in Fig. 2(b) and Fig. 2(c), respectively. The first control sample is defined by $E_T^\text{sig} \leq 3.0$ GeV$^{1/2}$, $\min \Delta \phi (E_T, \text{jets}) \geq 0.3$ rad; the second as $E_T^\text{sig} \geq 3.0$ GeV$^{1/2}$, $\min \Delta \phi (E_T, \text{jets}) \leq 0.3$ rad. The $b$-tag rate parametrization is found to predict the non-$t\bar{t}$ background to within 10% in the $4 \leq N_{\text{jets}} \leq 6$ region where 96.4% of the $t\bar{t}$ signal is expected. This value is thus adopted as the systematic uncertainty on the background prediction. Additional checks, using low jet multiplicity events from leptonic $W$ data samples, show agreement between observed and predicted $b$-tags to within the quoted uncertainty.

The sample selected with the optimized kinematical requirements described above and the requirement of at least one $b$-tagged jet consists of 106 events, containing a total of 127 $b$-tagged jets. The number of $b$-tagged jets yielded by background processes in that sample is expected to be $N_{\text{exp}} = 67.4 \pm 2.7 \pm 6.7$. The first uncertainty contribution is due to the limited number of events in the 3-jet sample used for the tagging rate parametrization, while the second contribution is the 10% systematic uncertainty on the $b$-tag rate parameterization discussed above (Fig. 2). The 597 pre-tag data events are expected to contain a non-negligible $t\bar{t}$ component, due to the $S/N$ enhancement provided by the kinematical selection, which yields a background overestimate. The $N_{\text{exp}}$ value is corrected, to $N_{\text{exp}} = 57.4 \pm 8.1$, to account for

---

**FIG. 1:** Tagging rate probability parametrization in the multijet sample as a function of jet $E_T$ (a), track multiplicity (b), and missing $E_T$ projection (c).

**FIG. 2:** Ratio of observed to expected $b$-tags as a function of the number of jets in the data before the optimized kinematical selection on $E_T^\text{sig}$ and $\min \Delta \phi (E_T, \text{jets})$ (a), and in control samples: $E_T^\text{sig} \leq 3.0$ GeV$^{1/2}$, $\min \Delta \phi (E_T, \text{jets}) \geq 0.3$ rad (b); and $E_T^\text{sig} \geq 3.0$ GeV$^{1/2}$, $\min \Delta \phi (E_T, \text{jets}) \leq 0.3$ rad (c).
TABLE I: Number of b-tagged jets expected from Monte Carlo $t\bar{t}$ production using $\sigma(t\bar{t}) = 6.1$ pb ($m_t = 178$ GeV/$c^2$), predicted by the tagging rate parametrization, and observed in the selected sample, as a function of the jet multiplicity. The total uncertainty on the number of predicted background b-tags is the sum in quadrature of the statistical uncertainty and of a 10% systematic uncertainty. The number of background b-tags corrected for the $t\bar{t}$ contamination in the pre-tagging data sample is also provided for the signal region. Uncertainties on signal contributions are statistical only.

In order to further establish the $t\bar{t}$ signal in the selected data we perform binned likelihood fits to kinematical distributions. The stability of the fitting technique is checked using simulations with known signal fractions. We fit $E_T$ and $\Delta\phi(E_T, \text{tagged jet})$ data distributions to the sum of a $t\bar{t}$ and a background template. The former is obtained from Monte Carlo $t\bar{t}$ inclusive events; the latter is derived from the tagging rate parametrization applied to the data. Results for the $\Delta\phi(E_T, \text{tagged jet})$ fit are displayed in Fig. 3. The fitted $t\bar{t}$ components in the selected data ($68 \pm 12\%$ and $44 \pm 12\%$ for the $E_T$ and $\Delta\phi(E_T, \text{tagged jet})$ fits respectively) are in agreement with the overall prediction calculated from b-tag counting, before any correction to account for the $t\bar{t}$ contamination in the pre-tagging data sample ($47\pm5\%$ determined comparing the number of expected and observed b-tags, for $N_{\text{jet}} \geq 4$, in Table I).

The efficiency of the trigger, the kinematical selection, and the b-tagging algorithm, are evaluated using inclusive $t\bar{t}$ Monte Carlo events. The combined efficiency of the trigger and kinematical selection amounts to $\epsilon_{\text{kin}} = 4.88\% \pm 0.43\%$ for a top mass of $m_t = 178$ GeV/$c^2$, where the dominant uncertainty is determined by the comparison of the results from the PYTHIA and HERWIG generators. Other sources of systematic uncertainty are evaluated by varying Monte Carlo generation settings with respect to the default values, and by applying systematic variations of the jet correction factors; the trigger acceptance uncertainty is determined by comparing trigger turn-on curves between Monte Carlo and data events (Table III). The average number of b-tags per Monte Carlo $t\bar{t}$ event is found to be $\epsilon_{\text{tag}} = 0.789 \pm 0.046$, adjusted for the $t\bar{t}$ acceptance.
and it is corrected according to the Monte Carlo secvtx efficiency scale factor of 0.909 ± 0.060 to reproduce the data b-tagging efficiency.

The cross section is calculated with a Poisson likelihood function in which the maximum likelihood solution for $\sigma(tt)$ is given by: $\sigma(tt) = \frac{N_{obs} - N_{\text{exp}}}{\epsilon_{\text{kin}} \cdot \epsilon_{\text{tag}} \cdot \mathcal{L}_{\text{int}}}$, where $N_{obs}$ and $N_{\text{exp}}$ are the number of $t\bar{t}$-tagged jets observed and expected from background events by the tagging rate parametrization in the selected data, and $\mathcal{L}_{\text{int}}$ is the integrated luminosity of the multijet data sample. The input parameters: $\mathcal{L}_{\text{int}}$, $\epsilon_{\text{kin}}$, $\epsilon_{\text{tag}}$, and $N_{\text{exp}}$ are subject to Gaussian constraints. With these input values we measure a top pair production cross section of $5.8 \pm 1.2^{+0.9}_{-0.7}$ pb. Additional samples of inclusive $t\bar{t}$ Monte Carlo events generated with different $m_t$ values in the range $[130, 230]$ GeV/$c^2$ are used to compute the cross section measurement dependence on $m_t$. The cross section measurement changes by ±0.05 pb for each ±1 GeV/$c^2$ change in the top quark mass from the initial value of 178 GeV/$c^2$. For instance, we measure $\sigma(tt) = 6.0 \pm 1.2^{+0.9}_{-0.7}$ pb assuming a top quark mass of 175 GeV/$c^2$. The change is due to the varying signal selection efficiency with top quark mass.

In conclusion we report the first measurement of the top pair production cross section of $\sigma(tt) = 5.8^{+1.5}_{-1.4}$ pb using an inclusive selection of $E_T$+jets $t\bar{t}$ decays. The result is complementary to other cross section analyses, maintains high sensitivity with respect to $W \rightarrow \tau \nu$ $t\bar{t}$ decays, and is in good agreement with SM calculations and previous measurements.

[3] The CDF II coordinate system uses $\theta$ and $\phi$ as the polar and azimuthal angles, respectively, defined with respect to the proton beam axis direction, $z$. The pseudorapidity $\eta$ is defined as $\eta = -\ln[tan(\theta/2)]$. The transverse momentum of a particle is $p_T = p sin(\theta)$ and the transverse energy is defined as $E_T = E sin(\theta)$. The missing transverse energy, $\not{E}_T$, is defined by $\not{E}_T = -\sum_i E_T^i \hat{n}_i$, where the index $i$ runs over all calorimeter towers with $|\eta| < 3.6$, and $\hat{n}_i$ is a unit vector perpendicular to the beam axis and pointing at the $i^{th}$ calorimeter tower.
