TWISTOR ACTIONS FOR SELF-DUAL SUPERGRAVITIES

LIONEL J. MASON AND MARTIN WOLF

Abstract. We give holomorphic Chern-Simons-like action functionals on super-twistor space for self-dual supergravity theories in four dimensions, dealing with $N = 0; \ldots; 8$ supersymmetries, the cases where different parts of the $R$-symmetry are gauged, and with or without a cosmological constant. The gauge group is formally the group of holomorphic Poisson transformations of super-twistor space where the form of the Poisson structure determines the amount of $R$-symmetry gauged and the value of the cosmological constant. We give a formulation in terms of a finite deformation of an integrable $\phi$-operator on a super-twistor space, i.e., on regions in $\mathbb{CP}^3$. For $N = 0$, we also give a formulation that does not require the choice of a background.

Key words and phrases. Twistor string theory, twistor theory, supergravity and contact (super)manifolds.
1. Introduction

Recently it has been discovered that $N = 8$ supergravity has better ultraviolet behaviour than has hitherto been anticipated, B jerrum - Bohr, et al. (2007), B em et al. (2007) and G reen et al. (2007). This has led some authors to speculate that it is possibly even finite. This improved behaviour relies on exact cancellations that do not follow from standard superymmetry arguments, Stelle (2005). One possible explanation arises from twistor string theory, W itten (2003) and B erkovits (2004).

The original twistor string theories by W itten and B erkovits correspond to conformal supergravity (together with supersymmetric Yang-Mills theory), B erkovits & W itten (2004). By gauging certain symmetries of the Berkovits twistor string, A bou- Z eit, H ull & M ason (2008) introduced a new family of twistor string theories some of which have the appropriate field content for Einstein supergravity (including $N = 4$ and $N = 8$). Such a twistor string formulation of Einstein supergravity could be an explanation for the possible ultraviolet finiteness of $N = 8$ supergravity if it were fully consistent in its quantum theory. However, it now appears that these twistor string theories are chiral, N air (2008), unlike the the original twistor string theories which were parity invariant. It remains a major open question as to whether a twistor-string theory exists that gives the full content of Einstein (super-)gravity even just at tree level.

An approach to understanding what the appropriate twistor string theory might be is via a twistor action, M ason (2005) and B oels, M ason & S kinne r (2007a, b). Such actions have two terms. The first on its own gives a kinetic term for all the fields, but with only the self-dual part of the interactions. The second gives the remaining interactions of the full theory and correspond to the instanton contributions in the twistor-string theory. In the case of $N = 4$ supersymmetric Yang-Mills theory, the self-dual part of the action on twistor space is a holomorphic Chern-Simons theory, W itten (2004), see also S okatchev (1995) for a closely related harmonic superspace action. B erkovits & W itten (2004) gave a twistor action for self-dual $N = 4$ conformal supergravity. The purpose of this paper is to give an analogous action in the case of self-dual $N = 8$ Einstein supergravity. This action is special to $N = 8$ supergravity in much the same way as W itten's Chern-Simons action is special to $N = 4$ supersymmetric Yang-Mills theory. It lends general support to the idea that twistor space has something special to say about full $N = 8$ supergravity and is suggestive of the existence of an underlying twistor string theory, perhaps even with explicit $N = 8$ supersymmetry as opposed to those of A bou-Z eit, et al. (2008) in which only $N = 4$ supersymmetry is manifest.

Penrose's non-linear graviton construction (1976) reformulates the local data of a four-metric with self-dual W eyl tensor into the complex structure of a deformed twistor space, a three-dimensional complex manifold obtained by deforming a region in CP$^3$. The space-time field equation in this case is the vanishing of the anti-self-dual part of the W eyl tensor, and in the A tiyah, H itchin & S inge r (1978) approach to twistor theory, this is reformulated as the integrability of the twistor algebroid complex structure. B erkovits & W itten (2004) introduce a version of conformal gravity with just self-dual interactions in which the underlying conformal structure...
is self-dual, but in which there is also a linear anti-self-dual conformal gravity field (a linearised anti-self-dual Weyl tensor $B$) propagating on the self-dual background. This has a Lagrange multiplier action (analogous to a $BF$ action)
\[ Z \left( B; C \right) d\text{vol}; \]

where $C$ is the anti-self-dual part of the Weyl tensor, and $(B; C)$ is the natural pairing. This can be extended to $N = 4$ supersymmetry. Berkovits & Witten (2004) gave a corresponding (supersymmetric) twistor action of the form $\text{vol} N$ where $N$ is the Nijenhuis tensor of the almost complex structure and $b$ is a Lagrange multiplier that doubles up as the Penrose transform of the field $B$ when the field equations are satisfied. In the non-supersymmetric metric case, this was extended to a twistor action for full (non-self-dual) conformal gravity in Mason (2005) with further supersymmetric extension and connections with twistor-string theory in Mason & Skinner (2008).

For Einstein gravity we wish to encode the vanishing of the Ricci tensor. In the non-linear graviton this can be characterised by requiring that the twistor space admits a blow-up over a $\mathbb{CP}^1$ together with a certain Poisson structure up to the box. Ward (1980) extended this to the Einstein case, with a cosmological constant; in this case, the twistor space is required to admit a holomorphic contact structure that is non-degenerate when the cosmological constant is non-zero, see Ward & Wells (1990) and Mason & Woodhouse (1996) for textbook treatments. So, for Einstein gravity, we are seeking a twistor action whose field equations not only imply the integrability of an almost complex structure, but also the existence of some compatible holomorphic geometric structure, for example the contact one-form in the case of the cosmological constant, or the blow-up together with a Poisson structure up to the boxes in the case of vanishing cosmological constant. The first task is to introduce suitable variables that encode the almost complex structure together with the relevant compatible geometric structure on the real six-manifold underlying the twistor space. This turns out to be a one-form with values in a line bundle, and we write down the appropriate field equations that must satisfy an action (depending also on a Lagrange multiplier field) that gives rise to them; the Lagrange multiplier field again corresponds to an anti-self-dual linear gravitational field propagating on the self-dual background via the Penrose transform when the field equations are satisfied.

Our primary exposition will focus on the $N = 8$ supersymmetric cases, and reduce them to the cases with lesser or no supersymmetry. Supersymmetric extensions of Penrose's non-linear graviton construction were first discussed by M. E. M. (1992a,b) (see also M. E. M. (1991,1992c)) based on work by M. in (1988) and developed further in A. Zeid, Hull & Mason (2008) and in Wolf (2007). That in Wolf (2007) gives a twistor description of four-dimensional $N$-extended, possibly gauged, self-dual supergravity with and without cosmological constant in terms of a deformation of a twistor space, a deformation of a region in $\mathbb{CP}^3$ endowed with

\[ 1 \text{See also Samann (2006) and Wolf (2006) and references therein for recent reviews of supersymmetric twistor and their application to supersymmetric gauge theories.} \]
an even holomorphic contact structure. Here we also discuss the di erent gaugings in the case without a cosmological constant. It is the ee the integrability of the almost complex structures of these twistor spaces together with the holomorphy of the appropriate geometric structures that correspond to the _eld equations for our twistor actions.

There are now a number of contexts arising from conventional string theory and M -theory in which the task of nding variables and action principles whose _eld equations encode the integrability of complex structures compatibly with some other geometric structure. In particular Kodaira-Spencer theory, Bershadsky et al. (1994), leads to _eld equations that imply the integrability of an almost complex structure compatible with a global holomorphic volume form on a six-manifold, yielding a Calabi-Yau structure. For a compendium of such theories and relations between them, including conjectured relations to twistor-string theory see Dijkgraaf et al. (2004). The situations considered here are distinct from those in Dijkgraaf et al. (2004), but given that one of the forms theories involved there is a self-dual form theory of four-dimensional gravity including a cosmological constant (see also Abou-Zeid & Hull (2006)) there may well be some important connections between these ideas.

The paper is structured as follows. In x2, we rst review the equations of self-dual supergravity, with cosmological constant and gauged R-symmetry, and then go on to review the various twistor constructions and give a brief proof of the version of the non-linear graviton construction for self-dual Einstein supergravity both with and without cosmological constant and di erent gaugings. In x3, we study minimal deformations and show that a deformation of the contact structure determines a deformation of the almost complex structure. We develop a non-projective twistor formulation that shows that this persists in the case of a nine deformation giving a compact form for the _eld equations, i.e., the integrability condition for the almost complex structure. In the case of maximal supersymmetry, N = 8, we present the twistor action and show that it gives the appropriate _eld equations. We give a brief discussion of its invariance properties and various reductions with lesser gauging, supersymmetry, or no cosmological constant.

A Chern-Simons action is always expressed in a given background frame and is not manifestly gauge invariant. In this gravitational context, our action is similarly not manifestly di eomorphism invariant; we require the choice of some background, which we take to be a solution to the _eld equations. However, we go some way towards an invariant formulation. We give an invariant formulation of the _eld equations in general, but only nd an explicitly di eomorphism invariant action in the N = 0 case with cosmological constant. We prove that on any smooth manifold of dimension 4n + 2 equipped with a complex one-form up to scale (i.e., a complex line subbundle of the complex cotangent bundle), then, if ^ (d f) = 0, and a non-degeneracy condition is satis ed, there is a unique integrable almost complex structure for which is proportional to a non-degenerate holomorphic contact structure. This idea can be used to give a covariant form of the _eld equations in general, and a covariant action in the N = 0 case.
In $x5$, we make some general concluding remarks. An action principle for $N = 8$ self-dual supergravity with vanishing cosmological constant has been obtained by Kamiya & Ketov (1998) in hamonic superspace for split space-time signature.\(^2\) In that work, hamonic superspace is the spin bundle of super-space-time and in Euclidean signature, it can naturally be identified with the super twistor space. However, their action uses structures pulled back from space-time (e.g., the Laplacian) that are not locally obtainable from the complex structure and contact structure on twistor space. It is therefore not possible to regard it as a twistor action. Nevertheless, their action is closely related to ours and we show that theirs can be obtained from ours by gauge fixing in appendix A. In appendix B we give a detailed discussion of the construction of the line bundle on a super-twistor space whose total space corresponds to a non-projective twistor space. In the appendix C, we discuss some alternative twistor actions.

2. Twistor constructions for self-dual supergravity

We work throughout in a complex setting. This can be understood as arising from taking a real analytic metric on a real space-time, and extending it to become a holomorphic complex metric on some neighbourhood $M$ of the real slice in complex space-time. We can straightforwardly restrict attention to Euclidean or split signature slice by requiring invariance under appropriate anti-holomorphic involutions (for Euclidean signature, these are discussed in appendix A). In the Euclidean case, one needs to restrict the number of allowed supersymmetries $N$ to be even.

2.1. Definitions, notation and conventions. We model our definition of chiral super space-time on the paraconformal geometries of Bailey & Eastwood (1991) (see also Wolf (2007)).

Definition 1. A right-chiral super space-time, $\mathcal{M}$, is a split super manifold of superdimension $4j\cdot N$ on which we have an identification\(^3\) $T\mathcal{M} = \mathcal{H} \mathcal{F}$, where $\mathcal{F}$ is the right (dotted) spin bundle of rank $2j$ and $\mathcal{H}$ is the sum of the left spin bundle $\mathcal{F}$ and the rank-0 bundle of supersymmetry generators and so has rank $2jN$. We will also assume that $\mathcal{F}$ and $\mathcal{H}$ are endowed with choices of Berezinian forms (so that $T\mathcal{M}$ does also).

This is the superspace one would obtain from a full super space-time by eliminating the left-handed fermionic coordinates, leaving only the right-handed ones in play. Being a split super manifold, it is locally of the form $\mathbb{C}^{4j\cdot N}$ with coordinates\(^4\) $(x^{-}; m^{-}) = x^0 - w$ with $x$ bosonic and $m$ fermionic where the indices range as follows: $0 = 1$ for left-handed two-component spinors, $0 = 1$ for right-handed spinors, $i;:::;m = 1;:::;N$ indexing the

\(^2\)A similar action for $N = 4$ supersymmetric Yang-Mills theory was discovered in the context of hamonic superspace by Sokatchev (1995).

\(^3\)By $T\mathcal{M}$ we will mean $T^{(1,0)}\mathcal{M}$. There will be no role for anti-holomorphic objects on $\mathcal{M}$.

\(^4\)The index structure on the bosonic coordinates in the curved case is not natural, but simplifies notation.
supersymmetry and $A = (\ i; \ j), M = (\ m; \ n)$; it will turn out in the following that it is natural, and simplifying in this self-dual context to group together the supersymmetry index $m$ and the undotted spinor index into one index $M$. We use the convention that letters from the middle of the alphabets are coordinate indices whereas letters from the beginning of the alphabets are structure frame indices.

The identification $T.M = \mathcal{H} \mathcal{F}$ will be spec'd by a choice of 'structure co-frame' e' given by the indexed one-form $s$

$$E_A^{-} = dx^M - E_M A^{-}$$

The dual vector fields will be denoted $E_A^{-}, E_A B^{-} = - A B^{-}$. We hence contracting a vector $\mathcal{E}V$ with a differential one-form we use the notation $\mathcal{E}V$.

With the capital R on an indices $A;B;\ldots$ ranging over both the bosonic ; $$\ldots$$ and the fermionic $ij;\ldots$ indices we use the notation $fAB;\ldots$ for graded sym-metrisation and $[AB;\ldots]$ for graded skew symmetrisation

$$(2.2a) \quad T_{fA;A;\ldots A;\ldots} = \frac{1}{n!} \cdot (\ ) \quad T_{A;\ldots A;\ldots}$$

$$(2.2b) \quad T_{[A;A;\ldots A;\ldots]} = \frac{1}{n!} \cdot (\ ) + \frac{n}{2p_n} \quad T_{A;\ldots A;\ldots}$$

where $p_n$ is the group of permutations of $n$ letters, $\ p\ j$ the number of transpositions in and the number of transpositions of odd indices.

For an index such as $A$ that ranges over indices for both odd and even coordinates, $p_n$ will denote the Gamma parity of the index, $p_n = 0$ for an even coordinate, and $1$ for an odd one so that a graded skew form $AB$ satisfies

$$A B = (\ )p_A p_B A$$

We introduce $-$ = $[\ldots]$ with $p_A = 1$ and $\ A = \ A$, and similarly for $\ B$.

In the supersymmetric setting, there is a distinction between differential and integral forms, the latter being required for integration, Mann (1989). Unless otherwise stated, all our forms will be differential.

2.2. Self-dual supergravity equations. We introduce connections on $\mathcal{H}$ and $\mathcal{F}$ represented by connection one-forms $A, B$ and $\ A, \ B$, respectively. These determine a connection $\gamma$ on $T.M$ by

$$\gamma V = dV^A - + V^B - B A + V^A - A$$

so that it preserves the factorisation $T.M = \mathcal{H} \mathcal{F}$. The fermionic parts of $A, B$ gauge the R-symmetry.

In this supersymmetric context, a choice of scale or volume form on $\mathcal{H}$ is a section of the Berezinian of $^1\mathcal{H}$. We can assume that the Berezinians of $\mathcal{H}$ and $\mathcal{F}$ have been identied so that the scale is determined by a section of the Berezinian of either $\mathcal{H}$ or $\mathcal{F}$. The connections can be chosen uniquely so that they preserve these sections of the Berezinians of $\mathcal{H}$ and $\mathcal{F}$ and so that the connection on $T.M$ has torsion with vanishing supertrace.\footnote{Special care needs to be taken for $N = 4$, Wolf (2007).}
that such choices have been made. In the formulae that follow, we will also assume that the connection is torsion-free as that is part of the self-dual Einstein condition (the torsion will not in general vanish on the full super space-time, only on this right-chiral (or left-chiral) reduced supermanifold).

The curvature two-form \( R^B_{A--} \) of \( \mathcal{H} \) decomposes into curvature two-forms for the connections on \( \mathcal{S} \) and \( \mathcal{F} \):

\[
R^B_{A--} = A^B R_{A--} + \ldots R^B_A : 
\]

Making explicit the form indices, we write the Ricci identities as

\[
\begin{align*}
\left[R^A_{\ldots} ; X^B \right] g^{CD} & = \left( \gamma^C (\varphi_a + \varphi_b) Y^C \right) R^A_{\ldots C} + \ldots R_{ABCD}^D; \\
(2.5) & + \left( \gamma^D (\varphi_a + \varphi_b) Y^D \right) - R^D_{ABCD} - ; \\
\end{align*}
\]

where \( V^A \) is a vector field on \( \mathcal{M} \).

In the torsion-free case, using the algebraic Bianchi identities, Prop. 2.6 of Wolf (2007) gives the decomposition of the curvature into irreducibles:

\[
\begin{align*}
(2.7a) & R^D_{ABC} - = 2 \left( \gamma^D (\varphi_a + \varphi_b) Y^C \right) R^D_{\ldots ABC} + \ldots R_{ABC}^D; \\
(2.7b) & C^D_{ABC} = C_{fABC} = 2 \left( \gamma^D (\varphi_a + \varphi_b) C_{fABC} \right); \\
(2.7c) & R^D_{AB -} = C^D_{AB-} + 2 \left( \gamma^D (\varphi_a + \varphi_b) \right) - R_{AB-}; \\
\end{align*}
\]

where the curvature tensors satisfy the algebraic conditions

\[
R^D_{AB} = R^D_{AB} = R_{AB}; \\
(2.8) C_{ABC} = C_{fABC}; \\
(2.9) C_{ABC} = 0; \quad AB = \{AB\}.
\]

Here, \( AB \) is a natural supersymmetric extension of the scalar curvature and will be set equal to the cosmological constant when the field equations are satisfied. (See Wolf (2007) for further details of the construction and properties of the connections.)

Definition 2. A right-chiral superspace will be said to satisfy the N-extended self-dual supergravity equations if

(i) the unique connection that preserves the given Berezinians of \( \mathcal{H} \) and \( \mathcal{S} \) is torsion-free and satisfies \( C_{AB-} = 0 \),

(ii) \( R^D_{AB-} = 0 \),

(iii) preserves some \( \mathcal{P}^{AB} = \mathcal{P}^{AB} \) of rank 2; and is at on the odd \( N \)-dimensional subspaces of \( \mathcal{H} \) that annihilates \( \mathcal{P}^{AB} \).

When \( AB = 0 \) it will be said to be Einstein, whereas if \( AB = 0 \) it will be said to be vacuum. When \( r = 0 \), the connection on \( \mathcal{H} \) is trivial in the odd directions and the supersymmetry generators are covariantly constant. For \( r > 0 \), a subgroup of the R-symmetry is gauged with gauge group an extension of \( SO(p;\mathbb{C}) \), the subgroup of \( SO(N;\mathbb{C}) \) that preserves \( \mathcal{P}^{15} \) the odd-odd part of \( \mathcal{P}^{AB} \). For \( r = N \), the gauge group is \( SO(N;\mathbb{C}) \).
Conformal supergravity corresponds to the more general situation where condition (i) alone is satisfied, and a natural supersymmetric analogue of the hypercomplex case corresponds to conditions (i) and (ii). In this work, we shall mostly be concerned with the situation where (i)(iii) are satisfied simultaneously.

There is only one possibility for the gauging in the Einstein case as follows:

Lemma 1. Either $P_{AB}$ and $A_B$ both have maximal rank and can be chosen to be multiples of each other's inverse, or $A_B = 0$.

Proof. Condition (iii) of Def. 2 implies that $(P_{\alpha} + P_{\beta})_\Gamma^\rho A_{BC} B^D \rho^E g^C = 0$ and taking a supertrace gives the equation

$$0 = \Gamma^{(P_{\alpha} + P_{\beta})_\Gamma^\rho A_{BC} B^D \rho^E g^C}$$

which quickly leads to the condition that $(P_{\alpha} A_{BC} B^D \rho^E g^C) = 0$. If this multiple is non-zero, $P_{AB}$ and $A_B$ have maximal rank and are multiples of each other's inverse. If this multiple is zero, the assumption on the rank of $P_{AB}$ implies that the rank of $A_B$ is less than or equal to $0$. The condition that the connections are on the subspace of $\mathcal{H}$ that annihilates $P_{AB}$ implies that $R_{ABC}^D e_0 = 0$ for all $e_0$ such that $P_{AB} e_0 = 0$. Symmetrizing over $ABC$ gives that $C_{ABC} D^e e_0 = 0$ so we must also have $c_{[A} e_0] = 0$. Note that for $N = 2$ the multiple is always zero.

It is a consequence of the Bianchi identities that $A_B$ is covariantly constant so that, when non-zero, we can set $A_B = P_{AB}$. When $A_B$ is non-trivial, the curvature is non-trivial on the odd directions of $\mathcal{H}$, and so the $R$-symmetry is therefore necessarily gauged with gauge group $SO(N - C)$.

We will see in §3.1 in the discussion of the deformations of twistor space how the different gaugings come about.

We also obtain $(P_{\alpha} + P_{\beta})_\Gamma^\rho A_{BC} B^D \rho^E g^C = 0$ and $r_{[A} C_{B} g_{CD}^E = 0$. The field equations of self-dual supergravity with zero cosmological constant lead to the Ricci identities

$$[r_{A} X]^{_B X} g^{_D D} = (P_{\alpha} + P_{\beta})_\Gamma^\rho A_{BC} B^D \rho^C = -C_{ABC}^D$$

which in turn imply Ricci-flatness of $\mathcal{H}$.

The self-dual supergravity equations on chiral superspace-time with vanishing cosmological constant first appeared in light-cone gauge and in their covariant formulation in the work by Siegel (1992).6

2.3. Twistor constructions. Flat twistor space is $\mathbb{CP}^\frac{1}{4N} n \mathbb{CP}^\frac{1}{4N}$ with homogeneous coordinates

$$Z_i = (i^A; \_),$$

where $i$ are bosonic coordinates and $\_i$ fermionic ones.

The supertwistor correspondence is between right-chiral complex super space-time $\mathbb{M}_{[N]} = \mathbb{C}^{42N}$ with coordinates $(x^\alpha; i^1) = x^A$, and is expressed by the incidence relation
\[(2.12)\]
$$t^A = x^A - i^1.$$  
By holding $x^A - i^1$ constant we see that points of $\mathbb{M}_{[N]}$ correspond to $\mathbb{C}P^1$'s in supertwistor space $\mathbb{P}^T_{[N]}$ with homogeneous coordinates $i^1$. Alternatively, by holding $i^1$ constant, we see that points in $\mathbb{P}^T_{[N]}$ correspond to $(2N)$-dimensional isotropic superplanes. In the curved case, both sides of the correspondence are deformed, but points of super space-time still correspond to $\mathbb{C}P^1$'s in supertwistor space (and points of supertwistor space to $(2N)$-dimensional isotropic subsupermanifolds of $\mathbb{M}$).

Bosonic twistor space will be denoted by $\mathbb{PT}$ and will be a deformation of some region in $\mathbb{C}P^3$, whereas a supersymmetrically extended curved twistor space will be denoted by $\mathbb{PT}^\mathcal{S}$ and will be a deformation of a region in $\mathbb{C}P^{3N}$. Similarly, a bosonic space-time will be denoted by $\mathbb{M}$ and a supersymmetric one (which will always in this paper be right-chiral) by $\mathbb{M}$.

We recall Witten's (1980) extension of Penrose's (1976) non-linear graviton construction to the case of non-zero cosmological constant:

**Theorem 1.** (Penrose 1976, Ward 1980)

(i) There is a natural one-to-one correspondence between holomorphic conformal structures $\mathfrak{g}$ on some four-dimensional complex manifold $\mathbb{M}$ whose anti-self-dual Weyl curvature vanishes, and three-dimensional complex manifolds $\mathbb{PT}$ (the twistor space) containing a rational curve (a $\mathbb{C}P^1$) with normal bundle $N = \mathcal{O}(1) - \mathcal{O}(1).

(ii) The existence of a conformal scale for which the trace-free Ricci tensor vanishes, but for which the scalar curvature is non-vanishing, is equivalent to $\mathbb{PT}$ admitting a non-degenerate contact structure.

(iii) The existence of a conformal scale for which the full Ricci tensor vanishes is equivalent to $\mathbb{PT}$ admitting a $SO: \mathbb{PT}! \mathbb{C}P^1$ whose base admits a Poisson structure with values in the pullback of $\mathcal{O}(2)$ from $\mathbb{C}P^1$.

Here, $\mathcal{O}(n)$ is the complex line bundle of Chern class $n$ on $\mathbb{C}P^1$.

The holomorphic contact structure is a rank-2 distribution $\mathcal{D} = T^{(1,2)}\mathbb{PT}$ in the holomorphic tangent bundle of $\mathbb{PT}$. The quotient detemines a line bundle $L = T^{(1,2)}\mathbb{PT}/\mathcal{D}$. It can be deduced dually to be the kernel of a holomorphic $(1;0)$-form $d$ on $\mathbb{PT}$. If $d$ is non-degenerate on $\mathbb{PT}$, then it is everywhere degenerate, and it determines a foliation whose leaves are the fibers of the projection $\mathbb{PT}! \mathbb{C}P^1$ and is the pullback of the one-form $\omega$ from $\mathbb{C}P^1$. Thus, $\mathcal{D}$ is the smooth foliation by these leaves.
L becomes the pullback of $O(2)$ from $\mathbb{CP}^1$. In the non-degenerate case, we can define a Poisson structure with values in $L$ to be the inverse of $\Phi$ on $D$. This has an analogue also in the degenerate case, now with values in $O(2)$ although its existence no longer follows from that of $\Phi$.

We can impose compatibility with, e.g., Euclidean reality conditions by requiring the existence of an anti-holomorphic involution $\Phi : PT \rightarrow PT$ without fixed points sending the given Riemann sphere to itself via the antipodal map. This induces a corresponding involution on $M$ giving a real slice on which the metric $g$ is real and of Euclidean signature.

The above theorem has a supersymmetric extension as follows:

**Theorem 2.** (i) There is a natural one-to-one correspondence between conformally self-dual holomorphic right-chiral space-time even and complex supermanifolds $\mathcal{M}$ of dimension $3N$ with an embedded rational curve (a Riemann sphere $\mathbb{CP}^1$) with normal bundle $N = O(1)^{2N}$.

(ii) Furthermore, $\mathcal{M}$ is a complex solution to the four-dimensional $\mathcal{N}$-extended self-dual supergravity equation with non-vanishing cosmological constant $\kappa$. The twistor space $\mathcal{PT}$ admits its a non-degenerate even contact structure.

(iii) $\mathcal{M}$ is a complex solution to the four-dimensional $\mathcal{N}$-extended self-dual supergravity equation with vanishing cosmological constant $\kappa$. The twistor space $\mathcal{PT}$ admits its a bion $\Phi : PT \rightarrow CP^{1|N}$ and a Poisson structure of rank $2N$ tangent to the frames with values in $O(2)$.

Here, $O(n) \cong CP^{n-1} O(n)$. The proof breaks up into three parts; further details of the non-degenerate cosmological constant case are given in Wolf (2007).

**Proof.** Part (i). Let $\mathcal{F} = \mathbb{P}(\mathcal{F})$ be the projective co-spin bundle over $\mathcal{M}$ with holomorphic projection $\Phi : \mathcal{F} \rightarrow \mathcal{M}$. Its frames $p^i(x)$ over $\mathcal{M}$ are complex projective lines $\mathbb{CP}^1$ with homogeneous frame coordinates $\mathcal{F}$. We define the distribution to be the rank-2$N$ distribution $D_{\mathcal{F}}$ on $\mathcal{F}$ given by

\[
(2.14) \quad D_{\mathcal{F}} := \text{span}_{\mathbb{C}} \mathcal{F}_A \mathcal{g} := \text{span} \left\{ -E_{A}^{+} + E_{A}^{-}, -1_{A}^{+} - 1_{A}^{-} \right\};
\]

where the $E_{A}^{+}$ are the frame fields and $1_{A}$ is the connection one-form on $\mathcal{F}$. A few lines of algebra show that $D_{\mathcal{F}}$ is integrable if and only if the connection is torsion-free and the $C_{AB}(\ldots)$ part of the curvature vanishes. In this case, the distribution $D_{\mathcal{F}}$ defines a foliation of $\mathcal{F}$. Working locally on $\mathcal{M}$, the quotient map will be our super twistor space, a $(3N)$-dimensional supermanifold denoted by $\mathcal{PT}$. The quotient map will be denoted by $q : \mathcal{F} \rightarrow \mathcal{PT}$ so that we have the double twistor space $\mathcal{PT} \dashv \mathcal{F} \rightarrow \mathcal{M}$. We note that we can form a non-projective super twistor space $\mathcal{F}$ by taking the quotient $\mathcal{F}$ by the distribution $D_{\mathcal{F}}$. The integral curves of the Euler vector $e = \text{span} \{ \mathcal{F}, \mathcal{g} \}$ are the frames $p^i(x)$ over $\mathcal{F}$ and $\mathcal{g}$ descends to give a vector $e$ on $\mathcal{F}$ which determines the double twistor space $\mathcal{PT}$.

Since $\mathcal{F}$ is a $\mathbb{CP}^1$-bundle over $\mathcal{M}$ and the frames are transverse to the distribution $D_{\mathcal{F}}$, the submanifolds $q(p^i(x))$ of $\mathcal{PT}$, for $x \mathcal{M}$, are $\mathbb{CP}^1$-s. In the other
direction, the supermanifolds $p(q^{-1}(2))!\mathcal{M}$, for $2\mathcal{P}\mathcal{T}$, are the $(2N)$-dimensional isotropic subsupermanifolds of $\mathcal{M}$ given by the projections of integral surfaces of $\mathcal{D}_\mathcal{P}$.

The inverse construction, i.e. starting from $\mathcal{P}\mathcal{T}$, follows by applying a supersymmetric extension of Kodaira's deformation theory (N. A. M. 1986). This allows one to reconstruct $\mathcal{M}$ as the moduli space of $\mathbb{C}P^1$'s that arise as deformations of the given $\mathbb{C}P^1$ which will correspond to some $2\mathcal{M}$. According to Kodaira theory, $T_x\mathcal{M} = H^0(\mathbb{C}P^1;\mathcal{N})$, where $\mathcal{N}$ is the normal bundle to the given $\mathbb{C}P^1$ $\mathcal{P}\mathcal{T}$, and in order that the moduli space exist, we require the vanishing of the first cohomology of the normal bundle $\mathcal{N}$. If the given $\mathbb{C}P^1$ arises as $p^{-1}(x)$ for some $x \in 2\mathcal{M}$, then $\mathcal{N} = O(1)^{2N}$: this can be seen by expressing it as the quotient of the horizontal tangent vectors to $\mathcal{F}$ at $p^{-1}(x) = \mathbb{C}P^1$, which can be represented by $T_x\mathcal{M}$, by $\mathcal{D}_\mathcal{P}$

\begin{equation}
(2.15)
\begin{align*}
0 ! & ! \mathcal{D}_\mathcal{P} !^p(x) ! T_x\mathcal{M} ! q\mathcal{N} ! 0 ;
\end{align*}
\end{equation}

Since the twistor distribution $\mathcal{D}_\mathcal{P}$ restricted to the base $p^{-1}(x)$ over $2\mathcal{M}$ is $O(1)^{2N}$, and $T_x\mathcal{M} = O^{2N}$, $\mathcal{N}$ takes the form $O(1)^{2N}$ as stated above. Kodaira theory in turn implies that we can reconstruct $\mathcal{M}$ as the moduli space of such $\mathbb{C}P^1$'s, and that the construction is stable under deformations of the complex structure on $\mathcal{P}\mathcal{T}$. Kodaira theory identifies the tangent bundle $T_x\mathcal{M}$ with the sections of the normal bundle, $\mathcal{N} = O(1)^{2N}$, and these, by an extension of Liouville's theorem, are linear functions of $\mathcal{A}$, i.e., $V^\mathcal{A}$, where the $\mathcal{A}$ index is associated to a basis of $\mathbb{C}^{2N}$. This gives the right-chiral manifold structure on $\mathcal{M}$, and it is easily seen that lines through a given point of $\mathcal{P}\mathcal{T}$ correspond to an integrable $(2N)$-manifold that will be an integral surface of the distribution $\mathcal{D}_\mathcal{P}$. Thus $\mathcal{D}_\mathcal{P}$ is integrable and the $\mathcal{M}$ is therefore conformally self-dual.

Part (ii). In the self-dual Einstein case with non-vanishing cosmological constant, we may introduce a one-form of homogeneity $2$ on $\mathcal{F}$ by

\begin{equation}
(2.16)
\begin{align*}
e &= - \epsilon \wedge - d \wedge \epsilon ;
\end{align*}
\end{equation}

where $\epsilon$ is the connection one-form on $\mathcal{F}$. The one-form automatically annihilates horizontal vectors and hence the distribution $\mathcal{D}_\mathcal{P}$. The form $\epsilon$ descends to $\mathcal{P}\mathcal{T}$ if and only if $\epsilon$ is annihilated by $\mathcal{D}_\mathcal{P}$ also. This characterizes the self-dual Einstein equations since when $C_{\mathcal{A}\mathcal{B}} = 0$, as follows from the conformal self-duality condition,

\begin{equation}
(2.17)
\begin{align*}
de &= r \wedge \epsilon \wedge + E^\mathcal{A} \wedge E^{\wedge \mathcal{A}} \wedge AB \wedge - E^\mathcal{A} \wedge E^{\wedge AB} \wedge - ;
\end{align*}
\end{equation}

and this is annihilated by $\mathcal{D}_\mathcal{P}$ if $R_{\mathcal{A}\mathcal{B}} = 0$. Thus, $\epsilon$ descends to $\mathcal{P}\mathcal{T}$, i.e., there exists a one-form on $\mathcal{P}\mathcal{T}$ such that $e = \epsilon$.

Non-degeneracy of the contact structure is the condition that $d$ is non-degenerate on the kernel $\mathcal{D}$ of $e$, or equivalently, the condition that the three-form $^\wedge d$ should be non-degenerate in the sense that for any vector $X$, $X( ^\wedge d ) = 0$. This non-degeneracy is equivalent to the non-degeneracy of $\mathcal{D}_\mathcal{P}$ on $\mathcal{M}$. Thus, $d$ defines a non-degenerate holomorphic contact structure on $\mathcal{P}\mathcal{T}$. 
Part (iii). In the self-dual vacuum case, we see that the connection on \( \mathcal{F} \) is at and a basis for \( \mathcal{F} \) can be found so that it vanishes. In this basis, the \( S \) are constant along the horizontal distribution on \( \mathcal{T} \), and so along the distribution (2.14). They are therefore the pullback of coordinates on \( \mathcal{PT} \). The condition that the connection is at on the annihilator of \( \Gamma^{AB} \) in \( \mathcal{H} \) means that there are \( N \) r covariantly constant sections \( \varepsilon_s \) of the odd part of \( \mathcal{H} \), \( s = r + 1; \ldots; N \). The forms \( \varepsilon^A = \varepsilon^s \) are therefore constant and, since the connection is torsion free, these forms are exact and equal to \( \delta^A \) for some odd coordinates \( \delta \). The \( N \) \( r \) functions \( s = \delta \) can be seen to be constant also along the twistor distribution (2.14). The global holomorphic coordinates \( (\delta; \delta) \) define a projection \( S : \mathcal{PT} ! \mathbb{CP}^{1|N} \) as promised. We now define the Poisson structure by considering a pair of local functions \( f, g \) on \( \mathcal{PT} \). Pulled back to \( \mathcal{F} \), they satisfy

\[
-E_A f = 0; \quad E_A g = 0
\]

and this implies that

\[
E_A f = _f A; \quad E_A g = _g A
\]

for some \( f_A \), \( g_A \) of weight 1 in \( \varepsilon \) (this follows from the standard fact that \( -b = 0 \) \( b = b \) for some \( b \) which follows from the two-dimensionality of the spin space and the skew symmetry of \( \varepsilon \)). We define the Poisson bracket \( ff \gg gg \) of \( f \) with \( g \) to be

\[
ff \gg gg = ( \partial^A (p_A + 1) f_A \Gamma^{AB} g_B )
\]

It is clear that this has weight 2 in \( \varepsilon \), but, as given, this expression only lives on \( \mathcal{F} \). However, it is easily checked that, as a consequence of the covariant constancy of the \( \Gamma^{AB} \), it is constant along the distribution (2.14) and descends to \( \mathcal{PT} \).

See appendix B for more on the non-projective formulation.

3. Twistor actions

In order to consider actions, we must allow our fields to go off-shell, and this is most straightforwardly done in the Dolbeault setting. We can take an almost complex structure that is not necessarily integrable to be the off-shell \( \varepsilon \), and regard the integrability condition to be part of the \( \varepsilon \) equations. In the following we will see that if we require the almost complex structure to be compatible with a Poisson structure or complex contact structure and the almost complex structure can be encoded in a complex one-form \( \omega \) needed up to scale.

In the following, we will mostly work 'non-projectively' i.e., on \( T_{\mathbb{N}} \varepsilon = \mathcal{C}^{4|N} \), or at least using holomorphic coordinates. This can also be identified as the total space of the line bundle \( \mathcal{O}(1) \) over \( \mathcal{PT} \). On this space, we have the Euler homogeneity vector \( \varepsilon \), and a canonically defined holomorphic volume form (an integral form in this supersymmetric context) of weight 4 \( \mathbb{N} \), the tautological form pulled back from \( \mathcal{B}er(\mathcal{PT}) = \mathcal{O}(N) \) satisfying \( L = (4 \mathbb{N}) \), where \( L \) is the Lie derivative along \( \varepsilon \). Similarly, will be a well-defined differential one-form of weight 2. See appendix B for further discussion.
Deformations of twistor space. For simplicity, we take the super twistor space $\mathcal{P} \mathcal{T}$ to be a deformation of at twistor space $\mathbb{P} \mathcal{T}^0$ with homogeneous coordinates as in the at case given by

\[ Z^I = (i^A;_i)_i = (Z^A;_A)_A \]

the latter form distinguishes between the odd, $i$ and the even, $Z^A$ coordinates. We also assume that we are given an "infinity twistor" a constant graded skew-bivector

\[ I^{ij} = \text{diag}(P^{AB};_A)_A \]

where

\[ P^{AB} = \text{diag}(P_{ij};_i)_i \quad \text{and} \quad P^{ij} = P^{(ij)};_i \]

When $= 0$, we will take $P^{ij}$ to be diagonal with $r$ ones and $N - r$ zeroes along the diagonal.

We also introduce the graded Poisson structure on homogeneous functions $f$ and $g$ by

\[ [f;g] = (J^{(p+1)};_p)_p \cdot I^{ij}(\partial;_i)_i ;_j \]

where we introduce the notation

\[ \partial_i := \frac{\partial}{\partial Z^i} ;_i \quad \text{and we will also use} \quad \partial_i := \frac{\partial}{\partial Z^i} ;^i \]

In ninesimally, a deformation of the alnost complex structure is represented by a holomorphic tangent bundle valued $(0;1)$-form $j$, where the deformed and undeformed anti-holomorphic exterior derivatives are related by $\theta = \theta_0 + j$. The first order part of the integrability condition (assuming that $\theta_0 = 0$) is $\theta_0 j = 0$. An in ninesim aldecomorph induced by the real part of a $(1;0)$-vector $\theta_0 X$ gives rise to the deformation $j = \theta_0 X$, so that the in ninesim al deformations of the complex structure modulate those obtained by in ninesim aldecomorphisms defines an element of the Dolbeault cohomology group $H^1(\mathbb{P} \mathcal{T};\mathcal{T}(1;0)\mathcal{P} \mathcal{T})$.

In order to impose the Einstein or vacuum conditions, we will also demand that the deformation preserves the Poisson structure $I^{ij} \partial_i \cdot \partial_j$ of weight 2. In this linearized context, we can ensure this by requiring that the deforming vector elds $j$ preserve the Poisson structure $L_j = 0$, where $L$ is the Lie derivative. This will follow if $j$ is an instanton with respect to $h$, i.e., if there exists a $(0;1)$-form $h$ of weight 2 such that

\[ j = J dh = (J^{p+1})_p \cdot \partial_i h_I^{ij} \partial_i j \]

If $h = 0$, we see that $j$ is $\partial((h))$ and so is pure gauge. Thus such deformations correspond to $h$ taken to be Dolbeault representatives for elements of $H^1(\mathbb{P} \mathcal{T};\mathcal{O}(2))$. The Penrose transform gives the identification between elements of $H^1(\mathbb{P} \mathcal{T};\mathcal{O}(2))$ and linearized self-dual gravitational elds, Penrose (1968,1976) and in the supersymmetric case this will give the whole associated linearized gravitational supermultiplet.

---

We could take a nite deformation of any curved integrable twistor space, but would then need more coordinate patches.
We now consider a finite deformation, again determined by \( \theta = dZ^a h_a \) which, at this stage, is an arbitrary (even) smooth function of \( (Z^1; Z^a) \) homogeneous of degree 2 in \( Z^1 \) and 0 in \( Z^a \), holomorphic in the \( Z^1 \) and satisfies \( Z^a h_a = 0 \); we will never allow any dependence on the complex conjugates of the fermionic coordinates.

We then define the distribution \( T^{(1;1)} \mathcal{F} \) of anti-holomorphic tangent vectors on \( \mathcal{F} \) by

\[
T^{(1;1)} \mathcal{F} = \text{span} \{ \frac{\partial}{\partial Z^1} \} = \text{span} \theta_1 + \{ p; (\theta; h_a) I^{(2)} \otimes \theta_1 ; \theta_1 ; \}
\]

This is to be understood as a finite perturbation of the standard complex structure on at super-twistor space with \( \theta \)-operator \( \theta_0 = dZ^1 \theta_1 \). The complex structure can be equivalently determined by specifying the space of (1,1)-forms as

\[
(1,1) \mathcal{F} = \text{span} \{ dZ^1 \} = \text{span} \{ dZ^1 + I^{(2)} \otimes \theta_1 \theta_1 \}
\]

The integrability condition for this distribution is

\[
I^{(2)} \theta_1 \theta_1 h_a + h_a \theta_1 h = 0 \quad I^{(2)} \theta_1 \theta_1 h + \frac{1}{2} [h; h_g] = 0;
\]

where the wedge product in the last expression is understood. When this condition is satisfied, not only is the almost complex structure integrable, but also the Poisson bracket of two holomorphic functions is again holomorphic. In the case that \( \theta_1 = 0 \), when the Poisson structure is degenerate, the coordinates \( \theta_1 \) and \( r \) as required for the characterization of a twistor space for a self-dual vacuum solution. Thus, in this case, equation (3.7) is the main equation.

In the Einstein case, we must produce a holomorphic contact structure. On the twistor space, introduce the contact structure

\[
\theta_1 = dZ^1 Z^j I_{1j};
\]

where

\[
(1) I_{1k} I_{1j} = \delta^j_j \quad \text{and} \quad I_{1j} = \text{diag}( P_{AB}; -); \]

For the Einstein case, from Thm. 2, we need to know that we have a holomorphic contact structure on the deformed space. The deformed one can be taken to be

\[
\theta_1 = dZ^1 Z^j I_{1j} = dZ^1 Z^j I_{1j} + Z^2 \left( \frac{\partial \theta_1}{\partial Z^1} \right) (Z^1 \theta_1 h = 0 + 2 h;)
\]

where the last expression follows from the homogeneity relation \( Z^1 \theta_1 h = 2 h \). The condition that \( \theta_1 = 0 \), \( D_1 \mathcal{F} = 0 \) is

\[
(3.10) \quad \theta_0 \theta_1 + \frac{1}{2} [h; h_g] = 0.
\]

Thus, integrability of the complex structure follows from the holomorphicity of the contact structure, which is \( \theta_1 = 0 \). (When \( \theta_1 = 0 \), \( \theta_1 \) remains holomorphic trivially.) Thus, not only is (3.10) our main equation in the Einstein case, it also implies (3.7) in the other cases, and so we will focus on this as the main equation in what follows.

\footnote{As in the linearized context, we eventually want to impose the Einstein condition on the space-time manifold. Therefore, we are only interested in a subclass of (finite) deformations \( \theta_0 \theta_1 + j \) with \( j \) given by \( j = dZ^a h_a I_{1j}^a = dZ^a (\theta_1 h_a I_{1j}^a \theta_1). \)
The choice of the Poisson structure reduces the d.i.eomorphism freedom to (infinite) Hamiltonian coordinate transformations of the form

\[ Z^i = [Z^i; g] \quad h \quad h + \chi ; \quad \text{with} \quad \chi = \Theta_0 + h; \quad g; \]

where \( \Theta \) is some smooth function of weight 2. Under this transformation, the 'curvature' \( \mathcal{F}(\Theta/\mathcal{M}) \) behaves as \( \mathcal{F}(\Theta/\mathcal{M}) = F(\Theta/\mathcal{M}) + F(\mathcal{M}/\mathcal{M}) + \mathcal{F}(\mathcal{M}/\mathcal{M}) \) with \( F(\mathcal{M}/\mathcal{M}) = \mathcal{F}(\mathcal{M}/\mathcal{M}) \); \( g \). Thus, the field equation (3.10) is invariant under these transformations.

We can see that, at least in linear theory, \( h \) encodes a supergravity multiplet as follows. The form \( h \) may be expanded in the odd coordinates as

\[ h = h_0 + \sum_{r=1}^{\chi} \frac{1}{r!} h_{r+1}; \quad h; \]

If we further linearise (3.10) around the trivial solution \( h = 0 \), it tells us that \( \Theta_0 h = 0 \), or equivalently, \( \Theta_0 h_0 = 0 = \Theta_0 h_{r+1}; \). Because of the gauge invariance of (3.11), which at linearised level reduces to \( h = \Theta_0 \), we see that \( h_0 = 2 \mathcal{H}^{(P \mathcal{T}/\mathcal{O}(2))} \) and \( h_{r+1} = 2 \mathcal{H}^{(P \mathcal{T}/\mathcal{O}(2))} \), where \( \mathcal{P} \mathcal{T} \) represents the body of the super manifold \( \mathcal{P} \mathcal{T} \) (so that \( \mathcal{P} \mathcal{T} \) is a finite deformation of \( \mathcal{P} \mathcal{T}^{(0)} \)). By virtue of the Penrose transform, Penrose (1968), \( h_0 \) corresponds on space-time to a helicity \( s = 2 \). While \( h_{r+1} \) to a helicity \( s = (4 - r) = 2 \). Hence, for maximally \( N = 8 \) supergravity, we nd \( (h_0) = (2; \frac{1}{2}; \frac{3}{2}; \frac{5}{2}; \frac{7}{2}; \frac{9}{2}; \frac{11}{2}; \frac{13}{2}; \frac{15}{2}; \frac{17}{2}; \frac{19}{2}; \frac{21}{2}) \) which is precisely the (on-shell) spectrum of \( \mathcal{N} = 8 \) Einstein supergravity; the subscript \( f \) refers to the respective multiplicity. A together, we see that a single element \( h = 2 \mathcal{H}^{(P \mathcal{T}/\mathcal{O}(2))} \) encodes the full particle content of maximally super symmetric linearised Einstein gravity in four dimensions.

In this linearised context, it is straightforward to see how the gauging works. The bundle of \( \mathcal{R} \)-symmetry generators on twistor space is the tangent bundle to the odd directions spanned by \( \Theta = \Theta^{(1)} \). The linearised variation in the \( \Theta \) operator on this bundle is \( \mathcal{P} \mathcal{H}^{(1)} = \Theta \), because the part of \( \Theta \mathcal{F}^{(1)} = \Theta \mathcal{F}^{(1)} \) tangent to the odd directions is \( (\Theta \mathcal{F}^{(1)} + \mathcal{P} \mathcal{H}^{(1)}) = \Theta \), and \( \mathcal{F}^{(1)} \) is skew symmetric in \( j \) and \( i \). Thus, in the case of non-degenerate \( \mathcal{P}^{ij} \), this gives an element of the Lie algebra of \( \mathcal{S} \mathcal{O}(N; \mathcal{H}) \), and so corresponds to the maximal gauging of the \( \mathcal{R} \)-symmetry, with gauge group \( \mathcal{S} \mathcal{O}(N; \mathcal{H}) \). When \( \mathcal{P}^{ij} \) has rank \( r \), for \( r < N \), the gauging of the \( \mathcal{R} \)-symmetry will be reduced to the subgroup of \( \mathcal{S} \mathcal{O}(N; \mathcal{H}) \) that preserves \( \mathcal{P}^{ij} \).

In the appendix, we compare our approach with that of Kamnas & Ketov (1998), and make some comments on the space-time fields in the non-linearised setting for zero cosmological constant.

3.2. Action functionals. We will be interested in integrating Lagrangian densities over twistor space for which we will need the holomorphic volume integral form

\[ N = \mathcal{D} (D Z^i) = \frac{1}{i} \mathcal{I} \mathrm{abc} D Z^a D Z^b D Z^c \quad \mathcal{D}^{i} \quad \mathcal{I} = \int_{\mathbb{R}} \]

which has weight \( 4 \). On account of the Berezinian integration rule \( d^{i} d^{j} = \delta^{ij} \), implying \( d^{i} = d^{i} d^{j} = \delta^{ij} \) for \( 2 \mathcal{C} \). Here, we use Manin's (1988) notation to
denote integral forms associated with a given basis of differential one-forms. We will not integrate over any complex conjugated odd coordinates.

For maximal supersymmetry, $N = 8$, we can write down an action functional reproducing the field equations (3.10) and hence also (3.7)

$$
S[h] = \sum_{\delta} \left( h^\delta \partial_\delta h + \frac{1}{4} h^\delta [h;hg] \right)
$$

(3.14)

where the integral form

$$
\mathcal{I} = \int (dZ^{-1}) = \prod_{abcd} \sum_{i=1}^{y^8} dZ^a \wedge dZ^b \wedge dZ^c \wedge dZ^d
$$

(3.15)

It can be seen that the weights balance as $h$ has weight 2, $[h;g]$ weight 2 and $g$ (respectively, $\mathcal{I}$) has weight 4. This is the only value of $N$ for which there is such a balance.

The action (3.14) is invariant under (3.11). This follows from the Bianchi identity for $F^{(0,2)}$,

$$
\partial_\delta F^{(0,2)} + [h;F^{(0,2)}]g = 0;
$$

(3.16)

implied by the (graded) Jacobi identity for the Poisson structure.

It is clear that the almost complex structure, integrability conditions and action formulation (the latter for $N = 8$) only depend on the Poisson structure $I^{ij}$ and not on $I_{ij}$ directly. It is also clear that if $I^{ij}$ is degenerate, the above field equations and action (the latter for $N = 8$) all make good sense, although the action most directly yields (3.10) rather than the super cially weaker equation (3.7) that is sufficient to determine the relevant structures on the deformed twistor space.

The action (3.14) can be compared with the Kodaira-Spencer actions introduced in Bershadsky et al. (1994), the compendium of topological M-theory related actions in Dijkgraaf et al. (2005) and the Lagrange multiplier-type action involving the Nijenhuis tensor given in Berkovits & Witten (2004) in the $N = 4$ case. Our action is local in contrast to distinction with the non-local Kodaira-Spencer action. Our action is given for a non-Calabi-Yau space (due the isomorphism (B.5), the holomorphic Berezinian is only trivial when $N = 4$). Ours is most closely related to that in Berkovits & Witten, although our basic variable, the one-form $h$ which is a potential for the deformat ion $j$, considered in deformation theory (i.e. $j$ is a holomorphic derivative of $h$) and is most naturally expressed for $N = 8$ rather than $N = 4$.

We close this subsection by discussing the cases with $N < 8$ supersymmetries. We start from the action (3.14) with $N = 8$ but restrict the dependence of $h$ on $i$ by requiring invariance under an $SO(8; \mathbb{C})$ subgroup of the R-symmetry. Thus, we set

$$
h = f + N + 1 \sum_{\delta} Z^\delta;
$$

(3.17)
where \( f \) and \( b \) are now one form s depending on the bosonic twistor coordinates and \( \eta^1 ;\cdots; \eta^N \), \( f \) has weight 2, and \( b \) has weight 6. We can now integrate out the anti-commuting variables \( \eta^{N+1};\cdots; \eta^8 \) and integrate by parts to obtain the action

\[
S[b;f] = \int\omega^b b^\gamma \Theta_0 f + \frac{1}{2} [f;fg] \quad (3.18)
\]

This action is now of \( BF \) form where \( b \) acts as a Lagrange multiplier for the field equation

\[
\Theta_0 f + \frac{1}{2} [f;fg] = 0 \quad (3.19)
\]

which, as we have seen, implies that integrability of the complex structure compatible with a holomorphic Poisson structure. Varying \( f \) yields the equation

\[
\Theta_0 b = 0 \quad (3.20)
\]

and, together with the gauge freedom \( b \equiv b + \Theta_0 \), this implies that \( b \) defines an element of the cohomology group \( H^1(P;\mathcal{F};\Theta(N;6)) \) and so is the Penrose transform of a super field of helicity \( 2 + N = 2 \).

4. Covariant approach, covariant action for \( N = 0 \) and special geometry

The above actions are non-covariant in the sense that they explicitly depend on the chosen background frame that dieomorphism invariance is broken. This is normal in the context of Chern-Simons actions for which a frame of the Yang-Mills bundle must be chosen. Nevertheless, we will see that at least for non-degenerate and \( N = 0 \) we can give a covariant version.

The geometric structure we are concerned with here is closely related to a (real)

six-dimensional special geometry introduced by Cap & Eastwood (2003). In their geometry, a real rank-4 distribution (subbundle of the tangent bundle) \( D \) is introduced and, if sufficiently non-degenerate and satisfying a positivity condition, it is shown that there is a canonically defined almost complex structure \( J \) for which the distribution is an almost complex contact distribution. Furthermore, the obstruction to the integrability of \( J \) is identified. Our situation is somewhat different in that the primary structure on a smooth manifold, \( P \), is a complex one-form defined up to complex rescalings (or more abstractly, a complex line bundle \( \mathcal{L} \)). This is more information in the sense that \( D \) is defined directly as the kernel of \( \Theta_0 \), but is only defined by \( D \) to up to \( \eta^1 a + b \), where \( a; b \) are complex valued functions on \( P \). Given \( D \), there is a unique choice of \( \Theta_0 \) that is compatible with the Cap-Eastwood almost complex structure but a priori, one does not know if that is the one that has been chosen. Our analogue of the Cap-Eastwood theorem works in higher dimensions also and we state it in greater generality than we need.

Theorem 3. Suppose that on a (smooth) manifold \( P \) of dimension \( 4n + 2 \) we are given a complex line subbundle \( \mathcal{L} \) of \( T P \), represented by a complex one-form defined up to complex rescalings. Suppose further that

\[
\wedge (d b)^{1,0} = 0 \quad \text{and} \quad \wedge (d b)^{0,1} \wedge (d b) \neq 0;
\]
then there is a unique integrable almost complex structure for which is proportional to a non-degenerate holomorphic contact structure. Here, \( (d \bar{\omega}) = d \wedge d \) (n-times).

**Proof.** We claim that, with the assumptions above, the \((2n+1)\)-form \( (d \bar{\omega}) \) is simple, i.e., that the space of vectors \( X \mathbb{A} (P \wedge \mathcal{C} \mathcal{P}) \) such that \( X \mathbb{A} (\wedge d \bar{\omega}) = 0 \) is \((2n+1)\)-dimensional. This follows because the kernel of \( (4n+1) \)-dimensional, whereas \( \mathbb{A} \) is a skew form on this kernel and so must have even rank. However, its rank is less than \( 2n+2 \) by \( (d \bar{\omega})^+ = 0 \) but greater than or equal to \( 2n \) because \( (d \bar{\omega}) \neq 0 \). Hence, the kernel of \( (d \bar{\omega}) \) is \((2n+1)\)-dimensional and we will take this kernel to be the space of anti-holomorphic tangent vectors spanning \( T^{(0,1)} P \). The condition that \( T^{(0,1)} P \) should contain no real vectors follows from the second assumption of the theorem.

We have that \( X \mathbb{A} (\wedge d \bar{\omega}) = 0 \), \( X \mathbb{A} (\wedge d \bar{\omega}) = 0 \) and we will use this latter characterisation of \( T^{(0,1)} P \) in the following.

We now consider the integrability of the distribution. Let \( X \) and \( Y \) satisfy
\[
(4.1) \quad X \mathbb{A} (\wedge d \bar{\omega}) = 0 = Y \mathbb{A} (\wedge d \bar{\omega});
\]
Then clearly \( X \mathbb{A} = 0 = Y \mathbb{A} \) and
\[
(4.2) \quad \wedge (X \mathbb{A} d \bar{\omega}) = 0
\]
so that \( X \mathbb{A} d \bar{\omega} \) and \( L_X \mathbb{A} \), and similarly for \( Y \). Here, \( L_X \) denotes the Lie derivative along \( X \). Thus,
\[
(4.3) \quad [X ; Y] \mathbb{A} = X (Y \mathbb{A}) = Y (X \mathbb{A}) = X \mathbb{A} (\mathbb{A} d \bar{\omega}) = 0
\]
since \( X \mathbb{A} = 0 = Y \mathbb{A} \) by assumption and so \( X \mathbb{A} (\mathbb{A} d \bar{\omega}) = 0 \) from above. Furthermore,
\[
(4.4) \quad [X ; Y] \mathbb{A} (\wedge d \bar{\omega}) = \wedge ([X ; Y] d \bar{\omega}) + d([X ; Y] \mathbb{A}) = \wedge (L_X L_Y \mathbb{A} L_X) = 0
\]
since \( L_X = X \mathbb{A} d \bar{\omega} \) and \( L_Y \mathbb{A} \), so \( L_X \mathbb{A} L_Y \mathbb{A} L_X \mathbb{A} \).

Thus, the almost complex structure is integrable.

In the twistor context, we will take \( P \) to be a six-dimensional manifold with topology \( U S^2 \) with \( U \mathbb{R}^4 \) and, as before, we shall denote it by \( P \mathbb{A} T \mathbb{P} \). With this theorem, then, our data is simply a complex line subbundle \( L \mathbb{A} C T \mathbb{P} \mathbb{A} T \) represented by a differential one-form \( S \mathbb{A} b \) with values in \( L \) subject to the open condition \( \wedge d \wedge d \bar{\omega} \neq 0 \). We will also require that the line bundle \( L \) has Chern class 2. The elliptic equation is \( \wedge (d \bar{\omega}) = 0 \). The \( N = 0 \) action above is simply
\[
(4.5) \quad S \mathbb{A} b = b \wedge (d \bar{\omega})
\]
where \( b \mathbb{A} T \mathbb{P} \mathbb{A} T \) is a Lagrange multiplier. Clearly, the elliptic equation obtained by varying \( b \) is \( \wedge (d \bar{\omega}) = 0 \), as desired. The action is clearly diffeomorphism invariant, and enjoys a gauge invariance given by \( b \mathbb{A} T \mathbb{P} \mathbb{A} T \) and \( b \mathbb{A} T \mathbb{P} \mathbb{A} T \mathbb{P} \).
a non-vanishing complex-valued function on $PT$. This gauge freedom corresponds to the fact that takes values in a line bundle $L$ which we shall also denote by $\mathcal{O}(2)$ since it becomes that on-shell, and hence $b$ is a differential one-form with values in $\mathcal{O}(6)$.

The action is also invariant under $b \mapsto b+\theta$, where $(d^* \theta)^{\wedge} = 0$, and the space of such is two-dimensional when the eik equations are not satisfied, but three-dimensional when they are. (When they are satisfied, this freedom can be used to ensure that $b$ is a $(0,1)$-form.) There is also a gauge freedom in $b$ obtained as follows. We can define a partial connection $\mathcal{O}$ on $\mathcal{O}(n)$ by defining, now assumed to be a section of $\mathcal{O}(6)$, $\mathcal{O}$ to be the differential one-form modulo the kernel of $\mathcal{O}$ if $\mathcal{O}$ is defined by $\mathcal{O} \wedge (d^* \mathcal{O}) = d(\theta)$. It is clear from this definition that the integrand of the action evaluated on such a $b = \mathcal{O}$ is a boundary integral, and so this represents a gauge freedom. On-shell, the above definition becomes trivial, and $\mathcal{O}$ needs to be defined a little differently by $\mathcal{O} \wedge \theta = d(\mathcal{O})$ and in this case it leads to an honest $\theta$-operator on the line bundles $\mathcal{O}(n)$.

The eik equation for $b$ is

\begin{equation}
(4.6) \quad dB \wedge dB \wedge (d^*) = 0
\end{equation}

and when the eik equation for $b$ is satisfied, this is the $\theta$-closure condition for sections of $(\theta^1)PT \rightarrow \mathcal{O}(6)$. Taking into account the gauge freedom $b \mapsto b+\theta$, with $\theta$ a section of $\mathcal{O}(6)$, $b$ will correspond to an element of $H^1(PT;\mathcal{O}(6))$.

Thus, solutions to the eik equations correspond to a complex three-dimensional manifold $PT$ with holomorphic contact structure, and the condition on the Chern class of $L$ implies that it satisfies the topological assumption of $W$ and $\theta$'s theorem, so that, if it contains a holomorphic rational curve of degree one in the $S^2$-factor, then it corresponds to a space-time $M$ with self-dual Einstein metric. The eik $b \in H^1(PT;\mathcal{O}(6))$ then corresponds via the Penrose transform to a right-handed linearized gravitational eik propagating on that self-dual background. Thus, we have the self-dual sector of non-supersymmetric Einstein gravity.

4.1. The supersymmetric case. In the supersymmetric situation, we will assume that $\mathcal{PT}$ is a smooth supermanifold with six real bosonic dimensions and $N$ complex fermionic dimensions. Without loss of generality, we can always assume that the supermanifold is split in the smooth category (Batheleur (1979)), and that locally the odd coordinates are $i, i = 1;\ldots;N$, and that we will only ever have holomorphic dependence on $i$, their complex conjugates will not enter the form algebra, so, in particular, the transition functions for the supermanifold will be holomorphic in $i$.

We can still encode the structure of a supersymmetric non-linear graviton into a complex contact form as follows. We will assume that $a$ is a complex differential one-form on the supermanifold $\mathcal{PT}$, again with only holomorphic dependence on the $i$, i.e., $a = dx^a + d^a$ where the $x^a$'s are the real bosonic coordinates on $\mathcal{PT}$, $a = 1;\ldots;6$, and $\theta$ and $\bar{\theta}$ are holomorphic in $\theta^a$.

\[\theta^a = d\theta_c + i\theta_c\bar{\theta}^c\]
with \( i \) odd and \( \epsilon \) even functions on \( \mathcal{P} \). On the body of the super manifold, \( i = 0 \), we can assume that we have the equations \( ^\cdot (d^i) = 0 \) as before, but these will not hold when \( i \neq 0 \), even for standard at supertwistor space as, in general, \( (d^i)^{\epsilon} 0 \) for an odd variable. Thus, we cannot express the conditions we need quite so simply in the supersymmetric case.

Nevertheless, much of Thm. 3 works in the supersymmetric case also. We will require, firstly, as a genericity assumption, that the complexified kernel \( \mathcal{C} \) of \( \mathcal{P} \) has dimension \( 5N \) (here we are taking \( \theta = \theta_i^+ \) and \( \theta = \theta_i^- \) to be independent). Secondly, we require that on this complexified kernel of \( \mathcal{C} \), the two-form \( d \) has rank \( 2N \) so that the kernel of \( ^\cdot d \) is \( 3N \) -dimensional and further, that \( \ker( ^\cdot d ) \) has no real vectors, i.e.

\[
\ker( ^\cdot d ) \setminus \ker( ^\cdot d^i ) = \emptyset \tag{4.7}
\]

The fact that we have required that \( ^\cdot d \) depends only on \( i \) and not \( \epsilon \) means that \( d \) annihilates \( \theta = \theta_i^+ \) for \( i = 1, \ldots, N \) and so the rank of \( d \) is at most \( 5N \) in any case. With these assumptions, the proof of Thm. 3 follows without modification to show that \( \ker( ^\cdot d ) \) is integrable and that \( ^\cdot d \) is a holomorphic complex contact structure so that

\[
T^{(0,1)} \mathcal{P} : = \ker( ^\cdot d ) \tag{4.8}
\]

The main field equation is therefore the condition that \( ^\cdot d \) annihilates a complex distribution of dimension \( 3N \). In the supersymmetric context, we do not yet have an equation analogous to the bosonic equation \( ^\cdot (d^\gamma)^1 = 0 \) for higher-dimensional complex contact structures nor an action that produces this condition as its Euler-Lagrange equation. As a consequence, we have so far been unable to find a covariant supersymmetric action functional.

5. Conclusions

Given that these actions are 'Chern-Simons-like' one is led to ask the extent to which they can be interpreted coherently as holomorphic Chern-Simons theories. Clearly, in some sense, the gauge group should be taken to be the di eomorphism of the supertwistor space that preserve the holomorphic Poisson structure. This is most easily made sense of in a complexified context so that the holomorphic twistor variables are freed up and become independent from the conjugate twistor variables. Then the theory becomes a complexified Chern-Simons theory with gauge group the holomorphic contact transformations of the holomorphic supertwistor space, a region in \( \mathbb{C} \mathbb{P}^{1,3} \), on the conjugate supertwistor space (which is just \( \mathbb{C} \mathbb{P}^{3} \) as we have no anti-holomorphic fermionic coordinates). A similar connection between the self-dual vacuum equations and a gauge theory with a di eomorphism group gauge group was given on space-time in Mason & Newman (1989) (here the gauge theory was the self-dual Yang-Mills equations); see also Wolf (2007) for a supersymmetric extension thereof.

The fact that Thm. 3 works in \( 4n + 2 \) dimensions is suggestive of applications of this framework to the twistor theory for quaternionic Kahler manifolds with
non-zero scalar curvature in 4n dimensions. It is straightforward to write down a
Lagrange multiplier action \( R^b \wedge (d^* \eta)^{n-1} \) analogous to our \( N = 0 \) action, but
with \( b \in (2n-1) \)-form, although in this context the interpretation of \( b \) is less clear.

An attractive feature is that we have a fully supersymmetrically invariant and
Lorentz invariant 0-shell formulation of the theory. However, we have so far been
unable to nd an action functional of \( N = 8 \) self-dual supergravity that does
not depend on a given integrable background. Such an action functional would,
however, be di erent as one would hope for an explicitly di eromorphic invariant
action principle for \( N = 8 \) self-dual supergravity. In particular, if one wishes to
be able to extend the ideas to the full theory along the lines of Mason (2005)
for conformal supergravity, then it would seem awkward to have to identify a
Minkowski background.

A task for the future is to start with the super eld expansions (in the non-linear
setting) of \( R \) and \( \eta \) and reproduce the covariant form of the eld equations and of
the action functional of \( N = 8 \) self-dual supergravity in four dimensions as given
in Siegel (1992). In the zero cosmological constant case, our twistor action and
eld equations must correspond via the Penrose transform to Siegel’s results.

Acknowledgments. We would like to thank Alexander Popov for a number of
important contributions to this work and Mohab Abou-Zeid, Rutger Böels, Daniel
Fox, Chris Hull, Riccardo Ricci, Christian Samann and David Skinner for useful
discussions. We would also like to thank the referee for useful suggestions. The

ENIGMA (contract number MRTN-CT20045652) and through the ESF M IS-
GAM network. The second author was supported in part by the EU under the
MRTN contract MRTN-CT2004005104 and by STFC under the rolling grant
PP/D0744X/1.

Appendix A. Prepotential formulation

The subject of this appendix is the comparison of Kamal’ & Ketov’s (1998)
approach with ours. Their formulation is based on an anti-holomorphic involution
which picks a real slice in complexed space-time being of split signature. Pretty
much the same holds true, however, for Euclidean signature and it is this latter
case we are interested in here. As already indicated, this works only for an even
number of supersymmetries. In the following, we shall use conventions from Wolf

A.1. Real structures on \( PT_{\mathbb{R}}^{2n+1} \) and \( M_{\mathbb{R}}^{2n} \). Let us rst consider the supertwistor
space \( PT_{\mathbb{R}}^{2n+1} = \mathbb{C}P^{3N} \cap \mathbb{C}P^{12n} \) with (homogeneous) coordinates \((z^A; \_)_A\) for at

---

10 See also Abou-Zeid & Hull (2006) for a space-time action for expanding about the self-dual
sector in the case of Einstein gravity.

11 Similar expansions for certain supersymmetric gauge theories were performed in Popov &
Wolf (2004), Popov & Samann (2005), Samann (2005), Popov, Samann & Wolf (2005) and Lechtenfeld &
super space-time $\mathbb{M}_{[N]} = \mathbb{C}^{4^{2N}}$. An Euclidean signature real slice follows from the anti-holomorphic involution without xed points: $PT^0_{[N]} \times PT^0_{[N]}$ given by

\[ (x^A; \bar{x}^\alpha) = (x^A; \bar{\alpha}) = (\bar{\alpha} \mathbb{C}_B A; C^{-\alpha}_{-\bar{\alpha}}); \]

where bar denotes complex conjugation and $(C_B)^A = \text{diag}(C)$, with

\[ (A.2) \quad (C_0) = \; ; \quad (C_1^j) = \text{diag}(j); \quad (C_0) = \; ; \quad = 0 \quad 1 : \]

We can extend to a map from a holomorphic function $f$ on $PT^0_{[N]}$ another holomorphic function by

\[ (A.3) \quad (f(\; )) = f(\; ); \]

By virtue of the incidence relation, $i^A = x^A - \bar{\alpha}$, we obtain an induced involution on $\mathbb{M}_{[N]}$ explicitly given by

\[ (A.4) \quad (x^A - \bar{x}) = x^B - \mathbb{C}_B A C^{-\alpha}_{-\bar{\alpha}}; \]

We shall use the same notation for the anti-holomorphic involution induced on the different (super) manifolds in the twistor correspondence. The xed point set of this involution, that is, $(x) = x$ for $x \in M_{[N]}$, define Euclidean right-chiral superspace $M_{[N]} = \mathbb{R}^{4^{2N}}$ inside $M_{[N]}$.

Following Atiyah, Hitchin & Singer (1978), the super twistor space $PT^0_{[N]}$ can be identified with

\[ (A.5) \quad \mathcal{O}(1) \; \mathbb{C}P^1 \quad \mathbb{C}P^1 \]

and so it can be covered by two (acyclic) coordinate patches $\mathbb{U}$ and coordinatised by $(i^A; \bar{\alpha})$, where $i^A$ are local bre coordinates with $i^A = i^{\bar{A}} = i^A = i^{\alpha}$ and $\bar{\alpha} = \bar{\alpha}$ are the standard local holomorphic coordinates on $\mathbb{C}P^1$, with $\bar{\alpha}$ on $\mathbb{U} \setminus \mathbb{U}'$, $PT^0_{[N]}$. On the other hand, since $PT^0_{[N]}$ is diemorphic to $M_{[N]}$, $S^2 = \mathbb{R}^{4^{2N}}$, one may equivalently coordinatised it by using $(x^A - \bar{\alpha})$, where are the standard local holomorphic coordinates on $S^2 = \mathbb{C}P^1$. Note that $(i^A; \bar{\alpha}) = (x^A - \bar{\alpha})$, where

\[ (A.6) \quad (\; ) := \; \quad \quad \text{and} \quad (\; ) := \; ; \]

The explicit inverse transformation laws are simply

\[ (A.7) \quad x^A = \frac{i^A + \bar{\alpha}}{\bar{\alpha}}; \]

where $\bar{\alpha}$ are similarly defined as in (A.6). Altogether, we have obtained a non-holomorphic bration

\[ (A.8) \quad : PT^0_{[N]} \times M_{[N]} : \]

Introduce

\[ (A.9) \quad (\; ) := \; ; \quad (\; \; ) := \; \; ; \quad 1 := \; = 1 + , \; ; \]
like for \( ^{\wedge} = \ ( \ - \) \). Then, due to the above diffeomorphism, we have the following transformation laws between the coordinate vector fields:

\[(A.10a) \quad \frac{\partial}{\partial x^A} = \ - \frac{\partial}{\partial x^A} + \ x^A \frac{\partial}{\partial x^A} \]

\[(A.10b) \quad \frac{\partial}{\partial x^+} = \ - \frac{\partial}{\partial x^+} + \ x^A \frac{\partial}{\partial x^A} \]

\[(A.10c) \quad \frac{\partial}{\partial x^-} = \ x^A \frac{\partial}{\partial x^A} \]

for the holomorphic tangent vector fields and

\[(A.10d) \quad \frac{\partial}{\partial x^A} = \ - \frac{\partial}{\partial x^A} + \ x^A \frac{\partial}{\partial x^A} \]

\[(A.10e) \quad \frac{\partial}{\partial x^+} = \ - \frac{\partial}{\partial x^+} + \ x^A \frac{\partial}{\partial x^A} \]

\[(A.10f) \quad \frac{\partial}{\partial x^-} = \ x^A \frac{\partial}{\partial x^A} \]

for the anti-holomorphic ones.

A.2. Comparison of the two approaches. In what follows, we shall restrict our discussion to the \( \mathbb{C} \) -patch only and for notational simplicity suppress the patch index. Of course, a similar discussion carries over to the \( \mathbb{C}^\ast \) -patch.

To begin with, let us write down the field equations (3.10) more explicitly. If we let the deformation be \( h = d! \ h \ + \ d \ h \), they read as

\[(A.11a) \quad \frac{\partial}{\partial x^A} h - \frac{\partial}{\partial x^A} h + \frac{\partial}{\partial x^A} h = 0 \]

\[(A.11b) \quad \frac{\partial}{\partial x^+} h - \frac{\partial}{\partial x^+} h + \frac{\partial}{\partial x^+} h = 0 \]

Using the incidence relation \( ^{\wedge} = x^A \) and the involutions introduced in the preceding subsection, \( h \) can also be expressed in the coordinates \( (x^A \; ;) \) as

\[(A.12) \quad h = \ ^{\wedge} \ dx^A \ + \ d \ ; \]

where \( = \ 1 \) \( \ C \ h \) and \( = h + x^A \).

In order to compare our approach with those by Kamas & Ketov (1998), we notice that their formulation deals with the 'vacuum case', i.e. with the case of vanishing cosmological constant. Upon also recalling point (iii) of Thm. 2, we must therefore ensure that the deformation of the super twistor space is preserved, and so (i) \( h \) is of the form

\[(A.13) \quad h = \ ^{\wedge} \ dx^A \ ; \]

i.e. \( = 0 \), \( h = x^A \) and (ii) the relative symplectic structure needs to be preserved which amounts to requiring a degeneracy of the Poisson structure \( ! = (I_i^j) \) introduced in x3.1 according to \( ! = (I_i^A) \). Notice further that \( h \) must be of weight 3 in order for \( h \) to be of weight 2.
Some algebra then reveals that in the ‘vacuum case’ the above equations for \( h \) and \( h \) translate into the following set:

\[
\begin{align*}
(A.14a) & \quad @ + \frac{1}{2} [ \phantom{1}; g = 0; \\
(A.14b) & \quad @ + 2 @ = 0;
\end{align*}
\]

where \( \Theta_a = -\Theta x^a - \) and \( \Theta_a = -\Theta x^a - \).

Before going any further, let us say a few words about gauge symmetries. The original equations for \( h \) transform covariantly under gauge transformations of the form \( h \rightarrow h + \xi \), with \( \xi = \Theta_0 + \xi h; \) \( g \) for some function of weight 2. However, the above equations will no longer transform covariantly under generic gauge transformations, since we have incorporated the constraint \( g = 0 \). Nevertheless, some residual gauge symmetry remains, and which is determined as follows. In order to preserve the constraint \( g = 0 \), we must have \( h = x^b \), where \( h \), \( x \) is transformation of \( h \) are determined by those of \( h \). It is not difficult to verify that the remaining gauge symmetry is given by the following transformation laws

\[
(A.15) \quad C = (\Theta + [ \phantom{1}; g]); \quad \text{with} \quad @ + 2 @ = 0.
\]

In particular, the last of these equations shows that the 2nd equation for \( h \) from above does not constrain any further, so that the only remaining \( \xi \) equation we are left with is

\[
(A.16) \quad @ + \frac{1}{2} [ \phantom{1}; g = 0.
\]

Since in particular \( = \Theta \) (see also Woodhouse (1985)), we have some function of weight 4 (recall that \( i = 1 \) is of weight 3) and \( i = 1 \), we end up with

\[
(A.17) \quad 2 + \frac{1}{2} ( \gamma^a \Theta_a \Theta_b \Theta_b = 0 \quad \text{and} \quad \Theta = \Theta \Theta);
\]

which is Kamal’s & Ketov’s (1998) result.

As before, in the case of maximal supersymmetry, \( N = 8 \), the \( \xi \) equations (A.17) can be derived from an action principle,

\[
(A.18a) \quad S[ \phantom{1}; \Theta] = \int \text{vol } 2 + \frac{1}{2} \gamma^a \Theta_a \Theta_b \Theta_b = 0.
\]

where the measure \( \text{vol} \) is given by

\[
(A.18b) \quad \text{vol} = d^6x \cdot 2 d d d^1 \Phi d
\]

It remains to give the super \( \xi \) expansion of \( \Theta \). For brevity, let us only discuss the \( N = 8 \) case. We end

\[
(A.19) \quad i \gamma^i i = \frac{1}{4} i \gamma^i i i 4; \quad \text{for} \quad r = 1; \ldots; 4;
\]

\[
(A.20a) \quad i \gamma^i i = \frac{1}{4} i \gamma^i i i 4; \quad \text{for} \quad r = 5; \ldots; 8;
\]
Here, \( i, \bar{i} \) and \( 1 \) are integers. Keeping in mind (A.13), we find the following space-time fields:

<table>

</table>

Table 1: Space-time fields and their helicities and multiplicities.

Appendix B. Holomorphic volume forms and non-projective twistor space

It is often convenient to work on non-projective twistor space \( T \) as many of the geometric structures can be formulated globally there and sections of the line bundles \( O(n) \) become ordinary functions of weight \( n \) under the action of the Euler vector field \( \phi = Z \frac{\partial}{\partial Z} \). In the curved case, as in the proof of theorem 2, the non-projective space can be defined as the quotient of the non-projective co-spin bundle \( \mathcal{F} \) by \( \mathcal{F}/Z \). We can also define it intrinsically as follows.

In the bosonic case, given a contact structure defined by a one-form \( \omega \) with values in a line bundle \( L \), we can see that \( \omega \) defines a (non-vanishing) section of \( O^3 PT \). Thus, we must have \( L^2 = (O^3 PT) \). In the negative, non-projective twistor space \( T_{[0]} = C^4 \) is the total space of the (tautological) line bundle \( O(1) \) over the projective twistor space \( PT_{[0]} \), and \( (O^3 PT)_{[0]} = O(4) \). In the general (non-supersymmetric) case, we can define the non-projective twistor space \( T \) to be the total space of the line bundle \( O(1) \) now defined to be the 4th root of \( O^3 PT \). If so, we see that \( L = O(2) \). The non-projective space has an Euler vector field that generates the holomorphic Poisson structure on \( PT \) with values in \( O(2) \).

In this context, \( \omega \) defines a 1-form of weight 2 on the non-projective space, and the non-degeneracy of the contact structure translates into the condition that the two-form \( \omega \) is non-degenerate as a two-form on \( T \) and being closed defines a holomorphic symplectic structure. Its inverse therefore defines a non-degenerate holomorphic Poisson structure on \( T \) of weight 2. This descends to give a Poisson structure on \( PT \) with values in \( O(2) \).

We can extend this reasoning to the supersymmetric case as follows. We assume a holomorphic differential one-form with values in a complex line bundle \( \mathcal{L} \). It defines as its kernel the contact distribution \( \mathcal{D} \), which now is of rank \( 2N \), leading to a short exact sequence as follows:

\[
\begin{array}{c}
\mathcal{D} \quad \mathcal{PT} \quad \mathcal{P} \\
(1,2) \quad (1,2) \quad (1,2)
\end{array}
\]

Since we assume that \( \omega \) defines a non-degenerate holomorphic contact structure, \( \mathcal{D} \) provides a non-degenerate skew form on \( \mathcal{D} \). Taking its Berezinian, we get an element:

\[
\text{Berez} \mathcal{D}) \quad 2 \mathcal{L}^2 \quad \text{Berez} \mathcal{D}^2
\]
(This follows from the fact that in the definition of the Berezinian, the odd-odd part of the matrix is inverted before its determinant is taken leading to inverse weights associated to the odd directions relative to their bosonic counterparts.) When $L$ has a square root, we can take its square root to get an isomorphism
\begin{equation}
\mathcal{P} \left( \text{Ber}(d \gamma) \right) : \text{Ber} \mathcal{D} \to \mathcal{L}^1 \overset{N=2}{\to} \mathcal{L}.
\end{equation}
The above exact sequence then gives an identification
\begin{equation}
\text{Ber} \left( \eta^2 \right) \mathcal{D} = \text{Ber} \mathcal{D} \to \mathcal{L} \overset{N=2}{\to} \mathcal{L}.
\end{equation}
and so finally we obtain the isomorphism
\begin{equation}
\text{Ber}(\mathcal{D}) \cong \text{Ber} \left( \eta^2 \right) \mathcal{D} = \mathcal{L}^{N=2}.
\end{equation}

We will take the body of the super twistor space to have topology $U \overset{S^2}{\to}$ where $U$ is an open subset of $\mathbb{R}^4$ (or more generally the total space of the projective co-spin bundle of a real spin four-manifold $M$). The assumption on the norm of a rational curve in super twistor space implies that the holomorpic Berezinian bundle $\text{Ber}(\mathcal{D})$ has Chern class $N=4$, and with the topological assumption we have made, this will have an $N=4$th root and we may introduce the (consistent) notation $O(n) = (\text{Ber}(\mathcal{D}))_{\eta=(N=4)}^\otimes$. Thus, $L = O(2)$ and $\text{Ber}(\mathcal{D}) = O(N=4)$.

Appendix C. Supersymmetric BF-type theory

In this appendix we wish to present an alternative interpretation of the holomorpic Chern-Simons one-type theory (3.14). We shall see that this theory can be viewed as a certain supersymmetric holomorpic BF-type theory. In what follows, we will borrow ideas of Witten (1989).

To begin with, consider some $(0;1)$-dimensional space $\mathcal{J}$ with odd coordinates $^1$ and $^2$, which we collectively denote by $\eta$. On $\mathcal{D} \mathcal{J}$, we may introduce a $(0;1)$-form $H$ of weight $2$ according to
\begin{equation}
H = h + ^1b^2.
\end{equation}
Here, $h$ and $b$ are even and $^2$ are odd $(0;1)$-forms of weight $2$ on $\mathcal{D} \mathcal{J}$. As before, we assume that these forms have no dependence on the $^1$ coordinates.

In analogy to (3.14), we may consider the action functional
\begin{equation}
S \left[ h; b ; \right] = d^1d^2 \int \frac{1}{8} \gamma h \wedge \Theta_0H + \frac{1}{2} H \wedge \Theta_0^\dagger \gamma h ; g ; \Theta_0^\dagger ; \Theta_0^\dagger ; g ; \Theta_0^\dagger ; \Theta_0^\dagger ; g ;
\end{equation}
A short calculation reveals that this action reduces after integration over the coordinates to
\begin{equation}
S \left[ h; b; \right] = \int \frac{1}{8} \gamma h \wedge b \wedge F \left( \gamma h \wedge b \right) \frac{1}{2} \gamma h \wedge b \wedge F \left( \gamma h \wedge b \right) \Theta_0^\dagger .
\end{equation}
The equations of motion that follow from this action are
\begin{align}
(C \text{Aa}) & \quad F \left( \gamma h \wedge b \right) = 0; \\
(C \text{Ab}) & \quad \Theta_0^\dagger b + \gamma h ; b g = \frac{1}{2} \left[ ; g ; \right]; \\
(C \text{Ac}) & \quad \Theta_0^\dagger + \gamma h ; g = 0;
\end{align}
The first equation is the eik equation (3.10). Note that for \( \theta = 0 \) we get (3.18).

The supersymmetry transformations are straightforwardly worked out as they follow from in nes in al translations in the odd coordinates. We end

\[
(C.5) \quad h = \ ; \quad b \text{ and } b = 0;
\]

with \( f \); \( g = 0 \). Therefore, the supersymmetry holomorphic BF-type action (C.3) can also be written as

\[
(C.6) \quad S[h; b; ] = \frac{1}{2} S[h];
\]

where \( S[h] \) is the action (3.14).
