Abstract

We discuss the phenomenology of strange-quark dynamics in the nucleon, based on experimental and theoretical results for electroweak form factors and for parton densities. In particular, we construct a model for the generalized parton distribution that relates the asymmetry $s(x) - s(x)$ between the longitudinal momentum distributions of strange quarks and antiquarks with the form factor $F_1^s(t)$, which describes the distribution of strangeness in transverse position space.

1 Introduction

The distribution of strange quarks and antiquarks is a nontrivial aspect of nucleon structure. Whereas the presence of these non-valence degrees of freedom is not surprising, given that gluons can split into $s$ pairs, their relative abundance compared with $u$ and $d$ pairs reflects the role of quark masses in nonperturbative dynamics. Furthermore, asymmetries in the distribution of $s$ and $s$ are not generated by the simple splitting $g^* s s$ and hence are footprints of more subtle dynamical mechanisms. Quantities that have received considerable attention in the recent literature are form factors of electroweak currents, which are accessible through parity violation in elastic lepton-nucleon scattering, and the difference between the momentum distributions of strange quarks and antiquarks, which in particular shown to be relevant for the determination of the weak mixing angle from deep inelastic neutrino-nucleon scattering [1]. In the present work we point out interrelations between different measures of strangeness and connect two of them quantitatively in a particular model.
A number of quantities related to strangeness in the nucleon are matrix elements of local operators. In view of our remarks in the previous paragraph, it is important to note the behavior of these operators under charge conjugation. In particular, the electromagnetic current is C odd and hence sensitive to the difference between contributions from p and s. In contrast, operators like the axial vector current, the energy-momentum tensor or the scalar current are C even and thus add the contributions from p and s. Large values of nucleon matrix elements would be more surprising for C odd operators than for C even ones, since for C odd operators they necessitate in parton states beyond simple quark fluctuations.

The unpolarized parton densities s(x), s(x) and their longitudinally polarized counterparts are defined as usual quark and antiquark densities of the proton as

\[ u(x) = \int dx H^q(x,t); \quad d_H^q(x,t) = \int dx H^q(x,t); \quad \Pi^q(x,t) = \Pi^q(x,t); \quad (1) \]

where the different signs on the r.h.s. reflect the different behavior of vector and axial vector operators under charge conjugation. H^q(x,t), E^q(x,t) and \Pi^q(x,t) respectively correspond to H^q(x; = 0; t), E^q(x; = 0; t) and \Pi^q(x; = 0; t) in the notation of [3,4]. Taking t = 0 and x > 0 we obtain the usual quark and antiquark densities of the proton as

\[ H^q(x;0) = q(x); \quad H^q(x;0) = \bar{q}(x); \quad \Pi^q(x;0) = \Pi^q(x;0) = q(x); \quad \Pi^q(x;0) = \Pi^q(x;0) = q(x); \quad (2) \]

A two-dimensional Fourier transform with respect to t gives the so-called impact parameter densities

\[ q(x;b) = \frac{Z}{2 \pi} e^{ib} H^q(x,t = 0); \quad \bar{q}(x;b) = \frac{Z}{2 \pi} e^{ib} H^q(x,t = 0); \quad (3) \]

which specify the spatial distribution of quarks or antiquarks with longitudinal momentum fraction x in the transverse plane, where the impact parameter b is the transverse distance of the parton from the center of the proton [5]. In impact parameter densities \( q(x;b) \), \( \bar{q}(x;b) \) for longitudinally polarized quarks and antiquarks in a longitudinally polarized proton are obtained from \( H^q(x,t) \), \( E^q(x,t) \) in full analogy to [3]. The Fourier transforms of \( E^q(x,t) \), \( E^q(x,t) \) describe the dependence of the impact parameter distribution of unpolarized quarks or antiquarks on transverse nucleon polarization [5].

The distributions just introduced are connected with the form factors mentioned above by sum rules, i.e. by integrals over the momentum fraction x. In particular, the lowest momentum states

\[ F^q_1(t) = \frac{d^2}{dx} H^q(x,t); \quad F^q_2(t) = \frac{d^2}{dx} E^q(x,t); \quad (4) \]

\[ F^q_1(t) = \frac{d^2}{dx} H^q(x,t); \quad F^q_2(t) = \frac{d^2}{dx} E^q(x,t); \quad (5) \]

give the strange Dirac and Pauli form factors, which are defined as

\[ \Pi(p^0) = \frac{p^0}{2m_p} u(p) \quad \Pi(p^0) = \frac{p^0}{2m_p} u(p); \quad (6) \]

\(^1We recall that the scalar current is relevant in connection with the pion-nucleon term, see e.g. [2].\)
where \( t = (p^\mu p^\nu)^2 \) and \( m_p \) is the proton mass. Their normalization is

\[
F_1^s(0) = 0; \quad F_2^s(0) = s; \quad (7)
\]

where the first condition reflects that the proton has no net strangeness, whereas the second condition involves the strangeness magnetic moment \( s \). Note that the contributions of \( F_1^s \) and \( F_2^s \) to the electromagnetic form factors of proton and neutron appear with a charge factor \( e_0 = 1 = 3 \). The sum rules \( (3) \) and \( (4) \) involve the difference of quark and antiquark distributions, as it must be for form factors of the current \( s \). Taking the Fourier transform as in \( (3) \) we see that

\[
Z \frac{d^2}{(2\pi)^2} e^{ibt} F_1^s(t = 0) = Z_1 \int_0 dx \ s(x; b) \ s(x; b) \quad (8)
\]

describes the difference between the transverse spatial distributions of strange quarks and antiquarks, averaged over their momentum fraction \( x \). Similarly, the Fourier transform of \( F_2^s \) describes the difference dependence of the impact parameter distributions on transverse nucleon polarization.

Further important momentum are

\[
A_{2p}^s(t) = \int_0 dx xH^s(x; t) = \int_0 \ dx xH^s(x; t) + H^s(x; t); \quad (9)
\]

which is a form factor of the energy-momentum tensor for strange quarks, and the strange quark contribution to the axial form factor,

\[
F_A^s(t) = \int_0 dx H^s(x; t) = \int_0 \ dx H^s(x; t) + H^s(x; t); \quad (10)
\]

which contributes to elastic lepton-nucleon scattering via Z exchange. Both form factors belong to charge-conjugation even currents and thus sum over quark and antiquark distributions.

Using \( (2) \) we can connect the values of form factors at \( t = 0 \) with momenta of the usual quark and antiquark densities. In particular, the first condition in \( (7) \) is equivalent with \( \text{hs} \ \text{si} = 0 \), where we introduced the shorthand notation

\[
h_f i = \int_0 dx f(x); \quad (11)
\]

In contrast, we have non-zero values for

\[
A_{2p}^s(0) = h x(s + s) i; \quad F_A^s(0) = h s + s i; \quad (12)
\]

which respectively give the fractional contributions of strange quarks and antiquarks to the longitudinal momentum and to the spin of the proton. There is no analogous relation for the second condition in \( (7) \) since \( E^s(x; t) \) and \( E^s(x; t) \) do not reduce to any parton density for \( t = 0 \). Let us however mention that their Fourier transform with respect to \( t \) satisfy positivity constraints involving the unpolarized and polarized quark or antiquark densities \( (6) \).

In order to obtain a quantitative feeling for the role of strange quarks and antiquarks in the proton, we briefly review in Sect. 2 the current experimental knowledge of the form factors \( F_1^s \) and \( F_2^s \) and of strange parton distributions. In Sect. 3 we mention a number of approaches to calculate the form factors and the momentum asymmetry \( s(x) \ s(x) \) theoretically, which will indicate dynamical mechanisms that can give rise to these odd quantities. In Sect. 4 we develop a model for \( H^s(x; t) \), \( H^s(x; t) \) and use it to connect at a quantitative level the asymmetry \( s(x) \ s(x) \) with the form factor \( F_1^s(t) \). According to \( (3) \) we thus connect the asymmetry between strange quark and antiquark distributions in longitudinal momentum with the one in transverse spatial position. Our results are summarized in Sect. 5.
Table 1: Data for the strange form factors at low $t$. Statistical and systematic errors have been added in quadrature. We quote results for $G_M^s$ or $G_E^s + G_M^s$ and the equivalent ones for $F_1^s + F_2^s$.

2 Experimental results for strange form factors and parton densities

2.1 Electromagnetic form factors

The strange form factors can be extracted from parity violation in elastic electron scattering on a nucleon [7-14]. Experiments typically measure a linear combination of the electric and magnetic form factors $G_E^s$ and $G_M^s$ at a low value of the momentum transfer. This can of course be converted into a linear combination of $F_1^s$ and $F_2^s$, using the relations

$$F_1^s = \frac{G_E^s + G_M^s}{1 + t}; \quad F_2^s = \frac{G_M^s - G_E^s}{1 + t};$$

where $t = 4m^2$. Recent experimental results at low $t$ are compiled in Table 1. Inspection of the table reveals that only the strange Dirac form factor is fairly well determined, whereas $F_2^s$ suffers from large uncertainties. It is also evident that the recent HAPPEX data [14] have significantly smaller errors than the other measurements. Unfortunately the two form factor combinations given in [14] are for different values of $t$. The determination of the individual form factors therefore requires an assumption about their $t$ dependence. A simple way to proceed is to ignore the difference in $t$ of the two measurements. From the corresponding two entries in Table 1 one then obtains

$$F_1^s (t') = 0.01 G eV^2 = 0.003(12); \quad F_2^s (t') = 0.01 G eV^2 = 0.005(26).$$

This result is graphically represented in Fig. 1. The use of all data near $t = 0.1 G eV^2$ in Table 1 does practically not change $F_1^s$, whereas $F_2^s$ becomes substantially larger but stays within the error quoted in [14].

An alternative method has been used in [15], where a parametrization of the small $t$ behavior of the strange form factors was tried to all data below $t = 0.3 G eV^2$. With the results updated in [16], the authors of this study obtain [17]

$$F_1^s (t) = t 0.02(11) G eV^2; \quad F_2^s (t) = 0.01(25).$$
for \( t = 0.1 \text{ GeV}^2 \), which at \( t = 0.1 \text{ GeV}^2 \) is fully compatible with our simple estimate [14]. The analysis in [15,16] includes the data of the G 0 Collaboration [13] with their very fine binning in \( t \), which we have not listed in Table I.

We remark that the experimental values quoted here are subject to theoretical uncertainties due to the effects of two-photon and of \( Z \) exchange, which have been discussed in [18,20] and may not be negligible.

2.2 Unpolarized parton densities

The determination of parton densities (PDFs) from unpolarized hard scattering processes has made significant progress in recent decade, in particular thanks to data with high precision and a large kinematical reach from HERA and from the Tevatron. The knowledge of strange distributions is much less advanced, because the observables that dominate global fits of parton densities have little sensitivity to \( s \) or \( s \). This holds in particular for inclusive deep inelastic scattering (DIS) in kinematics where photon exchange is dominant. More specific constraints on \( s \) and \( s \) distributions come from fixed-target DIS experiments with and beam. Thanks to such measurements, there have recently been dedicated attempts to determine \( s(x) \) and \( s(x) \) without strong assumptions on their relation with the light sea quark distributions \( u(x) \) and \( d(x) \).

In Table 2 we give the moment of \( h_x(s + s) \) obtained in recent PDF extractions. The study in [21] was dedicated to strangeness and explored a number of \( t \) at NLO in \( s \). The extractions in [22,23] were performed at NNLO. The table also gives the moment of \( h_x(u + d) \), whose values range from 6.21 \( 10^{-2} \) to 6.79 \( 10^{-2} \) and thus show a much smaller spread than for \( h_x(s + s) \). The ratio of \( h_x(s + s) \) and \( h_x(u + d) \) varies between 0.36 and 0.72 and quantifies the suppression of strangeness in the light quark sea. We furthermore show the avor asymmetry \( h_x(u - d) \), which like \( h_x(s + s) \) is not generated by simple \( g! \) \( q \) splitting and hence requires more subtle dynamics in order to be nonzero. The ratio of \( h_x(u - d) \) and \( h_x(u + d) \) varies between 7\% and 14\%. The parton
The study in [30] additionally uses RHIC data for further constraints on densities corresponding to the entries in the table are plotted in Fig. 2. We note that there are no experimental constraints on $u(x) - d(x)$ at small $x$, so that the large difference between the results of [22] and [21, 23] for this combination of densities is a consequence of the different functional forms assumed in the two sets.

The CTEQ 6.5S study [21] also performed sets where $s(x)$ and $s(x)$ were allowed to be different. A key input for constraining this difference are the CCFR and NuTeV data for dimuon production in DIS [24]. The parameterization in [21] was chosen such that $s(x)$ and $s(x)$ has precisely one zero crossing. The resulting momentum asymmetry at scale $= 2$ GeV was found to be

$$\frac{h(x(s + s)i)}{h(x(u + d)i)} = 0.94 \times 10^3 \quad (\text{set } 1);$$

$$\frac{h(x(s + s)i)}{h(x(u + d)i)} = 2.9 \times 10^3 \quad (\text{set } 2);$$

where set 0 corresponds to the best fit, whereas sets 1 and 2 were chosen to give the smallest and largest values of $h(x(s + s)i)$, respectively. The ratio of $h(x(s + s)i)$ and $h(x(u + d)i)$ in the three sets has respective values $54\%$, $27\%$ and $72\%$, which is somewhat smaller than the ratio of $h(x(u + d)i)$ and $h(x(u + d)i)$ in the non-strange sector. The left panel in Fig. 3 shows the asymmetry $s(x)$ obtained in these sets. We note that the best fit (set 0) is quite similar to preliminary results obtained by the MSTW collaboration [25]. It should be emphasized that a wider range of shapes is obtained if one allows for a variation of the small-$x$ behavior of $s(x)$, which is not well constrained by data. This is documented in a previous study by CTEQ [26] and shown in the right panel of Fig. 3.

### 2.3 Polarized parton densities

The polarization of strange quarks and antiquarks in the proton is not well known at present, for similar reasons as in the case of unpolarized parton densities. Many determinations of polarized PDFs in the literature, such as those in [27-29], are restricted to the structure functions for inclusive DIS with electron or muon beam $s$, which does not permit a separate determination of strange densities. This is highlighted in the "valence" scenario of [27], which assumes $s(x) = s(x) = 0$ at the starting scale $= 0.63$ GeV of evolution. This gives a tiny momentum asymmetry $= 4 \times 10^3$ at $= 1$ GeV. The study in [30] additionally uses RHIC data for $0$ production, which has no particular sensitivity to strangeness either. A process that is specifically sensitive to strangeness is sem-inclusive kaon...
Figure 2: Different combinations of parton densities at $x = 2$ GeV. Left: comparison of the different sets from CTEQ 6.5S [21]. Right: comparison of set 0 from CTEQ 6.5S [21] with A lekhin 06 [22] and M RST 2006 [23].
production in DIS, which has been measured by HERMES [31]. The study by de Florian et al. [32] includes these data and gives two sets of \( s(x) \) corresponding to different fragmentation functions. It does not assume SU(3) symmetry in the polarized sea, allowing \( s(x) \) to differ from \( u(x) \) and \( d(x) \). We note that a recent analysis of seminclusive hadron production by COMPASS reported evidence that the polarized sea is not SU(3) symmetric and that \( u \) and \( d \) may have opposite sign [34]. All analyses performed so far assume \( s(x) = \bar{s}(x) \).

In Table 3, we list the values obtained in recent analyses for the first moment \( \langle h \rangle \) in DIS. Note that 1–2 times this moment gives the contribution of strange quarks and antiquarks to the total spin of the nucleon. The values from the analyses [27–30] have been obtained with parameterizations where the polarized sea quark densities are equal, \( u(x) = d(x) = s(x) \), so that they should not be regarded as specific determinations of the polarization of the strange sea. Rather, they indicate that the contribution of sea quarks to the nucleon spin is negative and of moderate magnitude. The different results of the study [32] illustrate that a specific decomposition of this contribution is currently affected with considerable uncertainties. The numbers do not suggest that the strangeness contribution to the nucleon spin is very much suppressed compared with the light avors \( u \) and \( d \), but further data and analyses are clearly necessary to settle this issue. As a further word of caution we remark that an important fraction of the moments in Table 3 comes from the region of small \( x \), where the polarized densities are not constrained by data. Quantitative discussions are given in [28, 31].

3 Theoretical approaches

3.1 Electromagnetic form factors

The strangeness contributions to the electromagnetic and axial form factors of the nucleon have been studied in a large number of theoretical approaches (with many studies focusing on the strange magnetic moment or the electric charge radius). Detailed reviews and discussions can be found in [7, 35, 36]. In Table 4, we list a small number of recent results for the strange Dirac form factor at
Table 3: Lowest moment of polarized parton densities. All analyses show set $s(x) = s(x)$, and all except for \cite{32} take $u(x) = d(x) = s(x)$. The corresponding PDFs have been determined at NLO accuracy in the MS scheme and refer to the scale $= 1$ GeV.

Table 4: Theoretical results for the strange Dirac form factor at $t_0 = 0.1$ GeV$^2$. The numbers for Refs. \cite{43-47} have been read off from graphs. The value in the last row has been obtained from $G_M^a(t_0)$ in \cite{49} and $G_M^a(0)$ in \cite{48} using the approximation $G_M^a(t_0) \approx G_M^a(0)$, which was also made in Fig. 2 of \cite{16}. Taking into account that $|\mathcal{F}_S^a(t_0)| < |\mathcal{F}_S^a(0)|$, it would increase the value of $F_1^a(t_0)$.

Taking into account that $\mathcal{F}_S^a(t_0) < \mathcal{F}_S^a(0)$, it would increase the value of $F_1^a(t_0)$.

The calculation of strange form factors is challenging in many theoretical approaches. A large number of studies are based on the meson cloud picture, where the nucleon fluctuates into a $K$ and a $\Lambda$ or $\Sigma$. The coupling to the strangeness current then proceeds through valence degrees of freedom, namely the $s$ in the kaon and the $s$ in the hyperon. Concerns have been raised about the quantitative reliability of such calculations, based on the possible in portance of unitarity corrections \cite{37} and of higher-mass states \cite{38,39} such as $K$-mesons \cite{39}. There seems to be no consensus about these issues in the literature, see \cite{40,41} and \cite{36}. We will not quantitatively use the meson cloud picture in the present work, but use it as a qualitative guide in Sect. 4.2. Chiral perturbation theory provides a systematic framework for calculations in terms of hadron degrees of freedom, but its predictive power for strange form factors is limited, as discussed in \cite{42}.

Kaons also play an essential role in chiral quark models such as the one in \cite{43}, where the nucleon is described in terms of three constituent quarks coupling to the pseudo-Goldstone bosons. In this
approach, non-zero strange form factors are due to the splitting of a u or d quark into a kaon and an s quark. The chiral quark soliton model [44] does not rely on the constituent quark picture, containing as degrees of freedom both quarks and antiquarks coupling to pions and kaons.

A different approach is based on dispersion relations, which represent the form factors for spacelike t in terms of an integral over their imaginary parts in the timelike region. The assumption that the dispersion integral is dominated by single vector meson states leads to the vector meson dominance approximation, which underlies many calculations of the strange form factors. A typical procedure is to x the relevant nucleon-meson coupling constants from the isoscalar electromagnetic form factors of the nucleon and then to predict the form factors of the strangeness current. Such analyses often obtain rather large couplings of the nucleon to the ! (782) and the ! (1020), see for instance [45]. These large couplings are in strong conflict with determinations from nucleon-nucleon potential studies [50, 51] or from dispersion relations for forward nucleon-nucleon scattering [52], with SU (6) symmetry [53], and in the case of the with the OZI rule. To understand why ts of nucleon form factors with a small number of vector meson resonances can give large couplings, we consider the simplified case of just two mesons with masses m1 and m2, 

\[
\frac{a_1}{m_1^2} + \frac{a_2}{m_2^2} = \frac{a_1(m_1^2 - m_2^2)}{m_1^2 m_2^2} + \frac{(a_1 + a_2)(t - m_1^2)}{(m_1^2 + m_2^2) t + t^2} \]

In order to obtain a 1=t^2 behavior of the isoscalar form factor at large t, one must have a1 = a2 to keep the term with t in the denominator small. At t = 0 the form factor is then approximately given by \(a_1(m_1^2 - m_2^2)\), and the small mass difference between \(m_1^2\) and \(m_2^2\) forces the couplings \(a_1\) and \(a_2\) to be large. Taking into account higher-mass resonances significantly reduces this trend. As an illustration, we examined the isoscalar nucleon form factors to a sum of contributions from \(N N \otimes N N\) and \(N N \otimes V\), with or without an additional contribution from \(V(1650)\). We require an asymptotic behavior \(F_1 V + F_1 n = 1/t^2\) at large t, which provides a linear relation between the different meson-nucleon couplings relevant to the Dirac form factors we obtain

\[g_{NN}^V = 9.3\]  
\[g_{NN}^V = 20\]  

in the without \(N N \otimes V\), where the couplings refer to the ground-state mesons and are denoted by \(G_{NN}^V\) and \(G_{NN}^V\) in [51]. Including the \(V(1650)\), we obtain a good description of the data with

\[g_{NN}^V = 4.9\]  
\[g_{NN}^V = 11.9\]  

where \(g_{NN}^V\) is fixed to a value as small as the data permits, in order to minimize the tension with the acceptable values obtained in [50, 52, 53]. Taking both couplings as free parameters we nd

\[g_{NN}^V = 0.6\] and \(g_{NN}^V = 14.9\). Similar values have been obtained in [54].

This simple exercise suggests to take with great care the corresponding predictions for strange form factors, where contributions from kaon resonances are strongly enhanced compared with those from \(V\) states. A more realistic treatment requires the inclusion of continuum states, as has for instance been done in [55, 56]. The analysis in [56] found that the inclusion of the \(K K\) and \(KK\) continua makes the interpretation of a residual resonance contribution ambiguous.

3.2 The strangeness asymmetry s(x) ~ s(x)

The meson cloud picture naturally induces an asymmetry in the momentum distribution of strange quarks and antiquarks, which was first observed in [57] and underlies many calculations [58(64). In
this picture, the densities of s and s in the nucleon are given as convolutions of the longitudinal momentum distributions of the kaon or hyperon within the nucleon and the valence distribution of s in the kaon or of s in the hyperon. A similar mechanism is realized in chiral quark models [65], where the constituent quarks of the proton can fluctuate into a kaon and a strange quark. There is a significant spread among meson cloud model predictions for the shape of s(x) s(x), including its sign and the number of zero crossings, see e.g. the comparative study in [63]. The inclusion of K fluctuations in [64] also had a significant effect, changing even the sign of the momentum asymmetry hx(s s) compared to the result with kaon fluctuations alone. We note that the predictions for s s in such models typically have a zero at a value of x much larger than 0.01 and are thus rather different from the results obtained in the PDF ts [21,25].

The study [66] pointed out that in perturbative evolution at three-loop accuracy and beyond, graphs with three-gluon exchange in the t-channel generate an s s asymmetry. Starting with s(x) s(x) at the low scale = 0.51 GeV, the authors of [66] find that s(x) s(x) for 2 GeV is positive at small and negative at intermediate to large x, with hx(s s) 5 10 4. This is much smaller than the central results in [21,25], which suggests that this perturbative mechanism plays only a minor role in the generation of the momentum asymmetry.

4 Relating the strange Dirac form factor to s(x) s(x)

We now formulate a model ansatz for the C odd part of the generalized parpton distribution H s at zero skewness, which will allow us to calculate the Dirac form factor F s from the phenomenologically extracted asymmetry s s of momentum distributions. Following previous studies of generalized parton distributions in the non-strange sector [5,68] (70), we assume an exponential dependence with an x dependent slope and set

\[ H^s(x; t) H^s(x; t) = s(x) s(x) e^{f_s(x)}; \]  

(20)

where for the slope we take the simple form

\[ f_s(x) = 0(1 - x) \log \frac{1}{x}; \]  

(21)

which was already proposed in [5]. With [3], it is easy to see that the slope function f_s(x) has a simple physical interpretation in terms of the average squared impact parameter

\[ R^{2H_i x} = \frac{d^2 b b^2 s(x;b) s(x;b)}{d^2 b s(x;b) s(x;b)} = 4f_s(x) \]  

(22)

associated with the difference between s and s distributions. As shown in [71], a finite average transverse size of parton configurations with x 1 in the nucleon requires H b x to vanish at least like (1 x) 2 in this limit, which is obviously satisfied for the ansatz [21].

In the opposite limit x 0, we use simple Regge phenomenology as a guide for our parametrization. The form [21] corresponds to the behavior H^s H^s x(t), which arises from the exchange of a single Regge pole with a linear trajectory (t) = (0) + qt, or from the superposition of several Regge poles with the same value of (0). This is a generalization to finite t of a small x behavior x for the usual parton densities, which is consistent with phenomenology. The leading Regge trajectory that can contribute to H^s H^s is the one for the u mesons, and assuming a linear form (t) = (0) + qt, one obtains (0) = 0.13 and (0) = 0.94 GeV 2 from the masses and spins of (1020) and (1850). This value of (0) is close to the one for other meson trajectories, such as the
one for the and ! The trajectory contributes to soft hadronic scattering processes like kaon-nucleon scattering or photoproduction of the meson. It is however neglected in most analyses of these processes (which is justified if the -nucleon coupling is sufficiently small, see our discussion in Sect.[21]). An exception is the analysis of the total kaon-nucleon cross sections performed by Barger and Olson [67], who found an intercept \( (0) = 0.33 \) of similar size as the result obtained from the hadronic spectrum. We emphasize that in our approach we do not need an explicit value for the -nucleon coupling, since the normalization in [20] is used by the difference s s of parton distributions.

We note that the CTEQ 6.5S densities at \( = 2 \) GeV are well approximated by

\[ x(s, s) \sim x^0 \]  

in the region \( 10^{-5} < x < 10^{-4} \), with \( x = 0.031; 0.023; 0.044 \) for the respective sets 0; 1; 2. This corresponds to \( (0) = 0.72 \), which is quite far from the values we estimate for the trajectory. There are however no experimental constraints for the behavior of s s at very small x, and a value of \( (0) \) between 0.1 and 0.4 is within the range for which a good description of all relevant data has been obtained in the CTEQ study [26].

Using an ansatz as in [20] for the valence combinations \( H^u \ H^u \) and \( H^d \ H^d \), we obtained in [69] a good description of the electromagnetic Dirac form factors of proton and neutron. Given the wealth of data in this case, we chose in that study more complicated forms than [21] for the profile functions \( f_3(x) \) and \( f_4(x) \). We find that for \( 10^{-4} < x < 0.1 \) they are both very well approximated by the form [21] with \( = 1 \) GeV \(^2\), which remains close to \( f_d(x) \) for \( x > 0.1 \). Given the fast decrease of \( f(x) \) with \( x \), the small-x region turns out to be most important for our calculation of F\(^S\). We take the ansatz [20] with the CTEQ 6.5S densities [21] at \( = 2 \) GeV as input, where the chosen scale is to be considered as a compromise between a small value appropriate for parton densities based on hadronic Regge phenomenology and a value where the densities are sufficiently constrained by experimental data. In the left panel of Fig.4 we show the values of F\(^S\)(t) obtained with the best t sets 0 and with the alternative t sets 1 and 2. The central curves are for \( = 1 \) GeV \(^2\) in [21], and the bands correspond to \( = 0.85 \) GeV \(^2\) and 1.15 GeV \(^2\). We regard this variation as an estimate of the parametric uncertainty within our model, with the lower value corresponding to the estimate of the trajectory from the meson masses. In the following we refer to the result with \( = 1 \) GeV \(^2\) and CTEQ 6.5S set 0 as our default prediction.

If instead of taking [21] we set \( f_5(x) \) equal to the profile functions \( f_0(x) \) or \( f_4(x) \) obtained in [69], the form factor lies within the bands in the given, except in the region where \( F_5(t) \) has its maximum. In that region, the difference of \( F_5(t) \) obtained with the different profile functions just mentioned is at most 5%. As a further alternative, we have made the ansatz [20] at scale \( = 1.3 \) GeV, which is the starting scale of the CTEQ parametrizations. Taking the profile function [21] with \( = 1 \) GeV \(^2\), we again obtain values within the bands of Fig.4, except for deviations of up to 5% around the minimum of \( F_5(t) \). Clearly, the largest spread in predictions for \( F_5(t) \) with our model due to the different parton densities used as input. To further explore this, we have taken the parametrizations from the CTEQ 6 study [26] at \( = 2 \) GeV, which provides a wider range of shapes as we have seen in Fig.3. The resulting curves for \( F_5(t) \) are shown in the right panel of Fig.4. We recall that sets 1 and 2 in [21] and sets B and B+ in [26] were chosen to minimize or maximize the momentum fraction. They are hence not preferred, although consistent with the data tied in [21,26].

We see that in all cases the form factor \( F_5(t) \) is quite small and fully compatible with the estimates [9] and [10] extracted from experiment. We remark that for most of our curves, a linear behavior \( F_5(t) \) at small x is not a good approximation for much above 0.1 GeV \(^2\).

It is instructive to compare our results with another small-nucleon form factor, namely the Dirac form factor \( F_5(t) \) of the neutron. Figure 6 shows data together with the default t from [69], which
Figure 4: The strange Dirac form factor obtained from the sum rule [3] with the model ansatz in [20] and [21]. Central curves are for $0 = 1 \text{ GeV}^2$ and bands for $0.85 \text{ GeV}^2 < 0 < 1.15 \text{ GeV}^2$. The corresponding parton densities are (from top to bottom): CTEQ 6.5S sets 2, 0, 1 in the left panel and CTEQ 6 sets B+, B, C, B in the right panel. The data point is our estimate $\langle 14 \rangle$ of $F_1^n$, and the dotted curve corresponds to the parameterization of $F_1^n$ discussed in the text.

Figure 5: Data for the neutron Dirac form factor and $F_1^n(t)$ from [69]. The dotted line corresponds to our default prediction for $F_1^n$, obtained with $0 = 1 \text{ GeV}^2$ and CTEQ 6.5S set 0. The curve is rescaled such that its minimum coincides with the one of $F_1^n$. 

13
we already mentioned in connection with the profile functions $f_u(x)$ and $f_d(x)$. The same parametrization multiplied by 0.5 is shown as a dotted curve in Fig.4. We recall at this point that

$$F_1^n(t) = \frac{2}{3} F_1^d(t) - \frac{1}{3} F_1^u(t);$$

where the labels on the r.h.s. indicate the quark flavor contributions to the Dirac form factor $F_1$ of the proton. The $t$ in [69] neglected the strange contribution in $F_1^n$ and in $F_1^s$. We see in Fig.4 that our estimates for $F_1^n$ are at most half as large in magnitude as $F_1^n$ for $t = 0.2$ GeV$^2$, so that at that point $\frac{1}{3} F_1^s$ contributes at most 1−6 to the neutron form factor. For higher $t$ we would that $F_1^n(t)$ decreases faster than $F_1^n(t)$, which we will explain shortly. Only at small $t$ do we need a stronger in variance of the strangeness contribution. If our estimate is correct, this is of relevance for the $v$-e analysis of the Dirac radius of the neutron, which in more familiar terms can be expressed through the electric radius and a contribution from the magnetic moment,

$$\frac{\hbar^2}{4m} = 6 \frac{dF_1^n(t)}{dt}_{t=0} = 6 \frac{dG_1^n(t)}{dt}_{t=0} \frac{3m}{2} \frac{n}{3} \frac{dF_1^n}{dt} + 0.127 \text{ fm}^2;$$

Concerning the proton form factor, we find that the values of $F_1^p(t)$ shown in Fig.4 amount to at most 3% of $F_1^p(t)$ at any $t$.

4.1 The shape of $F_1^p(t)$

Let us now discuss the general features of $F_1^p(t)$ that emerge with our model ansatz, where we have

$$F_1^p(t) = \int dx s(x) s(x) e^{ixz}(x);$$

$$\frac{d}{dt} F_1^p(t) = \int dx s(x) s(x) f_8(x) e^{ixz}(x);$$

For the neutron form factor the situation is slightly more complicated even if we neglect the strangeness contribution, since the $t$ in [69] required different profile functions for $u$ and $d$ quarks. Since their divergence is only moderate, the discussion of $F_1^n(t)$ is somewhat simpler.

With $f_8(x)$ being a decreasing function, the factor $e^{ixz}(x)$ increasingly suppresses small $x$ values in the integral [26] when $t$ becomes larger. For increasing $t$ the form factor $F_1^p$ is therefore connected with $s_1$ at increasing values of $x$. With the profile function [21] we obtain the Drell-Yan relation

$$p = \frac{1}{2}(1 + \frac{1}{2})$$

between the powers describing the asymptotic power law $F_1^p(t)$ for $t > 1$ and $s_1$ for $t < 1$ [69,71]. The behavior of $s_1$ of sea quark distributions falls off faster with $x$ than the valence distributions $u$ and $d$, which are relevant for $F_1^p$, so that one generally expects $F_1^p(t)$ to decrease faster than $F_1^p(t)$ with $t$. As Figs.4 and 5 show, this is indeed the case in our model.

In Fig.5 we show the integrands of $F_1^p$ and $dF_1^p=dt$ in [26] and [27]. The integrands are multiplied with $x$ in the plots, so that with the logarithmic scale for $x$ we obtain the form factor or its derivative as the area under the corresponding curve. For $t = 0$ the integrand of $F_1^p$ is $s(x) s(x)$, which gives a zero integral because of quantum number constraints. The integrand for the derivative $dF_1^p=dt$ has an extra factor $f_8(x)$, which enhances small $x$ values relative to larger ones. At $t = 0$ one therefore has $dF_1^p=dt < 0$ at $t = 0$ if $s_1$ is negative at small $x$ and positive at large $x$. This is the case for the CTQCD sets [21,26] except for sets 1 and B. As $t$ increases, the factor $e^{ixz}(x)$ suppresses small $x$ values in [27], and for sufficiently large $t$ the derivative $dF_1^p=dt$ has the opposite sign than at $t = 0$. For some $t$ one hence obtains a maximum or minimum of $F_1^p(t)$. The value of $t$ where this happens
Figure 6: Upper plots: the scaled integrands of $F_i^\alpha(t)$ and $dF_i^\alpha(t)=dt$ in (26) and (27), obtained with our default prediction. Lower plots: the corresponding scaled integrands for $F_i^\alpha(t)$ and $dF_i^\alpha(t)=dt$, obtained with the default $t$ in (69). The values of $t$ in the right panels are as for the corresponding curves on the left.
is larger for parameterizations of $s$ with zero crossing at larger $x$, as one can check by comparing Figs. 3 and 4.

Figure 5 also shows the integrands for $F_1^n$ and $dF_1^n/dt$ for the default model in [69]. The discussion for the sign of the derivative $dF_1^n/dt$ and the presence of a minimum of $F_1^n(t)$ proceeds in analogy to the case of the strangeness form factor. Since the zero crossing of $\frac{d}{d^2}(u - 4(t - u))$ occurs at much larger $x$ than the one of $s$ in the CTEQ 6.5S parameterizations, whereas the respective profile functions are similar, $F_1^n(t)$ assumes its maximum at significantly larger $t$ than $F_1^x(t)$.

Let us at this point mention the PDFs extracted in [72]. In contrast to the analyses by CTEQ [21,26] and MSTW [25], the strangeness asymmetry $x(s,s)$ in [72] has a zero at $0.8 < x < 0.5$ and a maximum at $x = 0.7$. Taking this distribution with the same profile functions $f_s(x)$ explored above, we obtain a form factor $F_1^x(t)$ with a very large maximum $F_1^x > 0.0025$ for $1 \text{ GeV}^2 < t < 2 \text{ GeV}^2$ and a slow decrease with $t$. In this case, the bulk of the form factor integral [26] comes from very large $x$, where we deem our model for the profile function $f_s(x)$ associated with sea quarks very insecure. Since the study [72] used inclusive cross sections for DIS but no dimuon production data to constrain $s$, we do not regard such a scenario as strongly motivated. This example illustrates how ever that within our model from eikonal strong changes in $s$ result in qualitatively different forms of $F_1^x(t)$, which may eventually be ruled out by data.

The relations between the $x$ dependence of $s$ and the dependence of $F_1^x(t)$ discussed in this subsection follow from the general features of our ansatz in [20] and [21] and will also hold for more complicated forms. The neutron form factor $F_1^n(t)$ and the combination $\frac{1}{2}(d - u)$ of valence distributions, which are both much better known than their strangeness counterparts, provide an example where these relations are indeed seen and corroborate our prediction for the behavior of $F_1^x(t)$ with a given form of $s(x)$.

### 4.2 A modified ansatz

Our ansatz in [20] is special in that it assumes a dependence in the form of a global factor multiplying $s(x)$ or $s(x)$. It implies that the difference $s(x; p) - s(x; b)$ of impact parameter densities has a Gaussian shape in $b$ and in particular does not change sign for given $x$. One may wonder whether this ansatz is too restrictive. The physical picture of meson cloud models for instance suggests that the typical transverse position of $s$ is smaller than for $s$, since the $s$ originates from a kaon, which due to its smaller mass tends to be at larger distances than the hyperon containing the $s$. If this effect is strong enough, one may have a node of $s(x; p) - s(x; b)$ in $b$.

It is however important to realize that at $x = 2 \text{ GeV}$, where we formulate our model, the individual distributions of $s$ and $s$ are not valence-like as they would be in a model valid at low resolution scale. For sets 0, 1, and 2 of the CTEQ 6.5S parameterization at $x = 2 \text{ GeV}$ we find

$$x(s+s) \sim 0.2x^{0.2}$$ (28)

in the region $10^{-5} < x < 10^{-4}$, which is to be compared with [23]. For $x < 10^{-2}$ the ratio $(s - s)/(s + s)$ does not exceed $1\%$ in absolute size. It is natural to assume that the bulk of $s$ and $s$ in that region is generated through gluon splitting $g \rightarrow ss$ as described by perturbative evolution. This mechanism does not introduce an asymmetry in the transverse distribution of $s$ and $s$. When introducing a more general ansatz for $H^s$, $H^s$, than [20] we should hence make sure that the strong cancellation between $s$ and $s$ at small $x$ takes place not only in the forward limit but also at nonzero $t$. With this in mind, we explore a variant of [20], given by

$$H^s(x,t) = H^s(x) = s(x)e^{\frac{d}{d^2}(x)}$$ (29)
with

\[ f_5(x) = 0 \left( 1 - x \right) \log \frac{1}{x} + A x \left( 1 - x \right)^2 ; \]

\[ f_6(x) = 0 \left( 1 - x \right) \log \frac{1}{x} + A x \left( 1 - x \right)^2 ; \]  

(30)

where the prefactor x in front of A and A guarantees the cancellation just discussed, as long as \( t A \) and \( t A \) are not too large. In the following we take values \( 2 \text{ GeV}^2 \) and \( 4 \text{ GeV}^2 \) for either A or A.

With \( 0 = 1 \text{ GeV}^2 \) this respectively corresponds to a change of \( f_5(x) \) or \( f_6(x) \) by a factor 1.2 and 1.4 at \( x = 0.2 \), which one may view as a typical momentum fraction for s and s in a model at low scale, where nonperturbative effects could generate an asymmetric distribution in impact parameter. In the left panel of Fig.7 we show the corresponding impact parameter densities \( s(x;b) \) and \( s(x;b) \) and see that they indeed have nodes in b when A or A is equal to 4 GeV^2.

The form factors obtained with this ansatz are shown in Fig.8. For A > 0, where s is concentrated at larger impact parameters than s, the form factor \( F_5^s \) is increased in size but not much changed in shape compared to our default prediction with A = A = 0. In contrast, we find that for sufficiently large A > 0 the form factor \( F_5^s \) changes sign at some finite \( t \). We can understand this at the level of the form factor integrand: for \( f_5(x) > f_5(x) \) the exponential factors in (28) give a stronger suppression in the first term, so that at large enough x and \( t \) one can have \( H^s(x;t) < H^s(x;t) \) despite \( s(x) > s(x) \). This is illustrated in the right panel of Fig.7.

As discussed above, the meson cloud picture suggests that s has a smaller rather than larger typical impact parameter than s, so that we do not see a particular physical motivation for our examples with A > 0. However, they show that certain nontrivial correlations between the x and b dependence of the s and s distributions can have quite drastic effects on \( F_5^s(t) \), which may be observable in experiments with sufficient sensitivity and kinematic coverage.
Figure 8: The strange form factor obtained with the ansatz specified in Fig. 7. The curve for \( A = A = 0 \) corresponds to our default prediction in the previous subsections.

4.3 Other form factors

With our model (20) for \( H^8 \) \( H^8 \) we can also evaluate the Mellin moment \( A_{3/2}^p(t) = \int_1^s dx x^2 H^8(x; t) \), which is a form factor of an operator with two covariant derivatives between the strange quark and its conjugate. The factor \( x^2 \) strongly suppresses small-\( x \) values, and with the CTEQ parametrizations for \( s \) \( s \) the integral is dominated by an \( x \) region where the integrand has a definite sign. As a consequence \( A_{3/2}^p(t) \) decreases monotonically with \( t \). Its value at \( t = 0 \) is tiny, ranging from \( 10^{-4} \) to \( 4 \times 10^{-4} \) for the CTEQ 6 and CTEQ 6.5S parametrizations at \( s = 2 \text{ GeV} \). Exceptions are the values \( 6 \times 10^{-4} \) and \( 10^{-3} \) for CTEQ 6B and CTEQ 6B+, respectively.

We do not attempt here to model the strangeness contributions to the energy-momentum and axial form factors, \( A_{3/2}^p(t) \) and \( F_{1/2}^p(t) \), which according to (9) and (10) are respectively related to \( s + s \) and \( s + s \). These distributions mix with gluons under evolution, which invalidates simple ansatzes based on Regge trajectories for their small-\( x \) behavior. This also holds at \( n = t \) (73). Since even the \( t \) dependence of \( H^u + H^d \) and \( H^u + H^d \) is barely constrained at present, we see no clear guidance for how to model profile functions of \( H^u + H^d \) and \( H^u + H^d \). We expect however that these distributions have no zeros in \( x \), which certainly holds for their values at \( t = 0 \) according to current PDF parametrizations. We therefore predict the corresponding form factors to decrease monotonically in absolute size, with values at \( t = 0 \) given by the moments in Tables 2 and 3.

5 Summary

We have discussed several measures of strangeness in the nucleon. Strange quarks and antiquarks are not particularly rare in the proton: their contribution \( h(x) (s + s) i \) to the nucleon momentum is only suppressed by about a half compared with the one from light flavor antiquarks, \( h(x) (u + d) i \). Their contribution \( h s + s i \) to the spin of the proton is not well determined at present, but there are no indications that it is very much suppressed compared with \( h u + d i \).

More subtle quantities are asymmetries between strange quarks and antiquarks, most notably the asymmetry between the parton densities \( s(x) \) and \( s(x) \), and the strange Dirac and Pauli form factors \( F_{1/2}^p(t) \) and \( F_{3/2}^p(t) \). A two dimensional Fourier transform of \( F_{1/2}^p(t) \) yields the difference of spatial
distributions for s and s in the transverse plane, whereas s(x) s(x) gives the difference of their distribution in longitudinal momentum. The two asymmetries are connected via the generalized parton distributions at zero skewness, for which we have made a model ansatz in order to explore this connection quantitatively. Using as an input different sets of s s distributions extracted by the CTEQ Collaboration, we find values of Fp 0 t 0.1 GeV 2 between 0.006 and 0.012, in good agreement with current experimental constraints. Many theoretical analyses of the electromagnetic nucleon form factors neglect the strangeness contributions. With our estimates this is at most a 3% effect for Fp 0 (t). However, Fp 0 (t) might amount to as much as 1 = 6 of Fp 1 (t) at t = 0.2 GeV 2 . For higher t the relative contribution quickly decreases, whereas for lower t it may even be larger.

The general features of our model ansatz for generalized parton distributions lead to correlations between the x dependence of s s and the shape of Fp 1 (t). The best fits in the PDF extractions [21,25,26] yield forms where s s is negative for small x and positive for large x. With our ansatz, this gives a negative derivative dFp 1 (t)/dt at t = 0 and a maximum of the form factor at some value of t. With a zero crossing of s s at x between 10 2 and 10 1 , we nd this maximum at t between 0.2 GeV 2 and 0.4 GeV 2 . Analogous correlations are seen to hold between the combination (d d) 1/2 (u u) of valence quark distributions and the neutron form factor Fp 1 (t), which we take as support for our predictions. Finally, a rapid decrease of s s with x results itself in a faster decrease of Fp 0 (t) compared with Fp 1 (t) for large t. It will be interesting to confront these predictions with future data from parity violating electron-nucleon scattering.
