We investigate the influence of primordial perturbations of the energy density and space-time metric on the generation of the lepton and baryon asymmetries. In the weak and strong washout regimes baryon isocurvature perturbations with amplitudes of the same order as those of the CMB perturbations are generated on scales of order of the respective Hubble scale. They are, however, completely washed out by baryon and photon diffusion at the later stages of the universe's evolution.

Keywords: Baryogenesis via Leptogenesis, inhomogeneous universe, baryon isocurvature perturbations

I. INTRODUCTION.

Recent oscillation experiments [1,2] have confirmed that the neutrinos have small but nonvanishing masses. An observation of neutrinoless double beta decay by the future experiments [3] would hint toward the existence of very heavy right-handed Majorana neutrinos which generate naturally small neutrino masses via the seesaw mechanism. The existence of the heavy neutrinos can also explain [4] the observed baryon asymmetry of the universe since the three Sakharov conditions [5] are easily fulfilled in the standard model supplemented by the right-handed Majorana neutrinos.

The seesaw and baryogenesis via leptogenesis mechanism are very attractive from a theoretical point of view. Unfortunately, there is still no compelling evidence for the existence of the heavy right-handed Majorana neutrinos. A part from the neutrinoless double beta decay experiments one can search for its signatures in accelerator experiments or in lepton flavor violating decays [6,7]. However, the corresponding amplitudes are highly suppressed by the large masses of the right-handed neutrinos.

During leptogenesis, processes with right-handed neutrinos in initial, intermediate or final states are not suppressed. In a completely homogeneous and isotropic universe the outcome of baryogenesis via leptogenesis is a single number: the baryon-to-photon ratio, which is constant over space. In an inhomogeneous universe the primordial perturbations of the energy density and space-time metric modulate leptogenesis and the generated baryon-to-photon ratio depends on the spatial coordinates. Thus instead of a single number we get a function of spatial coordinates which can, in principle, provide us with some additional information on the model parameters.

A general perturbation with arbitrary fractional overdensity in each component can be represented as a sum of adiabatic and isocurvature perturbations. For a purely isocurvature perturbation the sum of the fractional overdensities is zero. For a purely adiabatic perturbation the fractional overdensity in each matter component (baryons, photons, etc.) is the same and hence the baryon-to-photon ratio is constant over space. Consequently, a deviation of the baryon-to-photon ratio from its average value amounts to a baryon isocurvature perturbation. We estimate here amplitudes and scale dependence of the generated perturbations.

Baryon isocurvature perturbations are known to act primordial nucleosynthesis. The abundances of the produced elements sensitively depend on the local baryon-to-photon ratio and the total average abundances can be considerably different from those in the homogeneous universe [8,9,10,11]. They also affect the spectrum of the cosmic microwave background (CMB) radiation. Purely isocurvature perturbations produce a series of peaks in the CMB spectrum whose angular scales are approximately in the ratio 1 : 3 : 5 : · · · , whereas purely adiabatic density perturbations produce peaks whose angular scales are in the ratio 1 : 2 : 3 : · · · [12]. Current large-scale observations are consistent with the primordial perturbations being adiabatic. It is however possible that the upcoming experiments will find a small admixture of the isocurvature perturbations at scales smaller than 10 Mpc [13,14]; in particular the Planck satellite will be able to limit the amplitudes of isocurvature modes to less than 10% of the adiabatic mode [15,16]. The isocurvature component modulates the sound velocity in the plasma and the initial conditions for the CMB [17], and is expected to smear out the spectrum, i.e. change height and width of the peaks.

The outline of the paper is as follows. In section II we derive differential and integral forms of the Boltzmann equation and prove the gauge invariance of the latter one. The derived integral Boltzmann equation is used to analyze leptogenesis in section III, where the generated lepton asymmetry is related to the adiabatic energy
density and metric perturbations and possible velocity perturbation in the heavy neutrino component. Finally we summarize our results in section IV.

II. THE BOLTZMANN EQUATION

The general form of the Boltzmann equation is [13]

$$\frac{df}{d\tau} = \hat{C}[f]$$

(1)

where is the a ne parameter along a geodesic and the collision operator acting on the one-particle distribution function f.

Since the Boltzmann equation treats particles as on shell states, f is a function of space (time) coordinates x and three independent components of the particle momentum P, or, alternatively, the particle kinetic energy E and unit momentum vector \(\hat{P}\). Thus we can rewrite the left-hand side of (1) using the chain rule

$$\frac{df}{d\tau} = \frac{df}{dx^i} \frac{dx^i}{d\tau} + \frac{df}{dP^i} \frac{dP^i}{d\tau} + \frac{df}{dE} \frac{dE}{d\tau} + \frac{df}{d\hat{P}} \frac{d\hat{P}}{d\tau} = \hat{C}[f];$$

(2)

The derivatives of E and \(\hat{P}\) can be calculated using the geodesic equation; the result depends on the space-time metric.

The space-time metric of the early universe, which was almost homogeneous and isotropic, can be split into a background part

$$g^0 = a^2(\tau) \text{diag}(1; 1; 1; 1);$$

(3)

where is the conformal time, and a small perturbation which reads [13]

$$g = a^2(\tau) \frac{2}{B_{ij}}(B_{ij} - g_{ij});$$

(4)

where a is the cosmic scale factor, , and B are scalar functions, and \(g_{ij}\) defined by

$$g_{ij} = \Theta_i \Theta_j - \frac{13}{3} \Theta_k \Theta_k E$$

(5)

is traceless. Note that the definition of used here differs by the \(\Theta_i \Theta_j E\) term from that used in [13]. This additional term will appear in the equation for the gauge transformation (13c) of later on.

A non-zero shift function B means that comoving worldlines and worldlines orthogonal to hypersurfaces of constant time are not collinear and we are dealing with a locally non-orthogonal coordinate system [13]. We avoid the associated unnecessary complications by setting B = 0 which is fulfilled, for instance, in all synchronous gauges and the longitudinal gauge.

Isotropy of the background space-time implies that the zero-order phase-space distribution functions are independent of the direction of the momentum vector, so that \(\frac{df}{d\tau}\) vanishes in the homogeneous universe de ned by \(g^0\) and is of rst order in the inhomogeneous universe de ned by \(g\). Isotropy also implies that in the homogeneous universe the momentum vector is conserved, so that in the homogeneous universe \(\frac{df}{d\tau}\) is of rst order as well. Consequently, the product of the two is of second order and the last term on the left-hand side of (2) can be neglected. Then the Boltzmann equation takes the form

$$\frac{df}{d\tau} = \frac{\partial f}{\partial x^i} \frac{\partial \hat{P}^i}{\partial \tau} + \frac{\partial f}{\partial E} \frac{dE}{d\tau} + \frac{\partial f}{\partial \hat{P}} \frac{d\hat{P}}{d\tau} = \frac{1}{g_0} \hat{C}[f];$$

(6)

The expression in the round brackets is (up to a sign) calculated to linear order in the small perturbations of the metric, and \(\frac{dE}{d\tau}\) is the Hubble parameter. In the longitudinal gauge \(B_{ij} = 0\) and the Boltzmann equation (6) reverts to that derived in [13].

As we are only interested in the total generated asymmetry, we integrate the Boltzmann equation (6) over the phase space. Integration of the rst term on the left-hand side gives the derivative of the particle number density n with respect to the time coordinate \(x^0\).

Since for a massive particle \(\frac{iv}{v^2} = \frac{iv}{v^2} = \frac{v^4}{v^2} = 0\), the second term on the left-hand side can be rewritten in the form

$$Z \frac{\partial f}{\partial x^i} \frac{\partial \hat{P}^i}{\partial \tau} = Z \frac{\partial f}{\partial x^i} \frac{\partial \hat{P}^i}{\partial \tau} = \frac{\partial (v^4)}{\partial x^i} \frac{\partial \hat{P}^i}{\partial \tau} = \frac{Z}{v^2} \hat{C}[f];$$

(7)

where \(v^4\) denotes the macroscopic three-velocity of the gas. In the early universe the macroscopic three-velocity is a rst-order quantity and therefore (up to second order corrections) is proportional to the corresponding macroscopic four-velocity \(v^4\) (recall that \(u^4 = a^4\)).

Since \(B_{ij}\) is of rst order, one can integrate the \(B_{ij}\) term in (6) over the isotropic zero-order phase-space distribution function. In this approximation the integration gives the same result for any \(1\) and therefore (recall that \(B_{ij}\) is traceless) this term vanishes to rst order.

Analogously, since \(B_{ij}\) is of rst order, one can again integrate the last term on the left-hand side of (6) over the phase-space using the zero-order phase-space distribution function; the integral vanishes due to the isotropy of the distribution function.

Upon integration by parts, the remaining terms take the form

$$Z (H - n) = \frac{\dot{n}}{\dot{g}} = \frac{\dot{g}}{\dot{g}^0} = \frac{a^3(1 + \epsilon)}{\dot{g}};$$

(8)

Using the fact that \(B_{ij}\) is traceless it is straightforward to check that \(g_1\) is the determinant of the spatial part of the metric.

Collecting all the terms we obtain the integral form of the Boltzmann equation

$$\frac{1}{g} \frac{\partial (nv^4)}{\partial x^0} + \frac{\partial (nu^4)}{\partial x^i} = -\frac{Z}{g_0} \frac{\hat{C}[f]}{E};$$

(9)
Equation (9) is a partial differential equation which is rather difficult to solve. However, if we neglect some further second-order terms, it can be substantially simplified. Since $u_{\mu}$ as well as the gradient of $n$ are of first order, their product can be neglected, so that $(nu_{\mu})'$ may be neglected. Next we introduce

$$n; P \exp \frac{R}{\mu} \text{d}x^0; \quad (10)$$

As can be checked by direct substitution, equation (9) is equivalent (up to the second-order term $s$) to the following equation for

$$1 = \frac{\theta}{\mu \theta} \frac{Z}{E} [\xi(E \mu)] \text{d} P; \quad (11)$$

where all the terms are evaluated at the same point in time.

Equation (11) is an ordinary differential equation with respect to the time coordinate. Any dependence of the generated lepton asymmetry on the space coordinates is "hidden" in the dependence of the metric and macroscopic parameters on the space coordinates. This substantial simplification is possible because we limit our analysis to linear perturbations here.

From (11) it is clear that $s$ is conserved if the collision term $s$ vanishes; that is, in the homogeneous universe replaces the particle number density per comoving volume $Y$.

Let us also note that equations (9) and (11) describe the development of the particle number density of a particular species and can be used in a universe with an arbitrary mixture of adiabatic and isocurvature perturbations.

The solutions of the Einstein equations give macroscopic parameters like the tem perature as functions of the time coordinate. Since the collision term depends explicitly on the inverse tem perature $z = \frac{2}{\theta}(\text{where } M_1 \text{ is mass of the lightest Majorana neutrino} \frac{20}{22})$ rather than on the time coordinate $x^0$, it is convenient to rewrite (11) as follows:

$$0 = P \frac{g}{\mu} \frac{Z}{E} [\xi(E \mu)] \text{d} P; \quad (12)$$

The dot denotes differentiation with respect to the time coordinate, whereas the prime denotes differentiation with respect to $z$.

The analysis of processes in the early universe is often complicated by the gauge choice. It is therefore important to check if the derived integral form of the Boltzmann equation is invariant with respect to the gauge transformation which preserves $B = 0$. Let us consider a transformation from synchronous to longitudinal coordinates. Small perturbations of the metric and u velocity in the longitudinal gauge are related to those in the synchronous gauge by

$$\eta_{(1)}(\mu) = \eta_{(s)}(\mu) \quad (13a)$$

$$u_{\mu(1)}(\mu) = u_{\mu(1)}(\mu) + a \theta_k \theta_k \eta_{(1)}; \quad (13b)$$

The same value of the proper time $t$ (which is gauge invariant by definition) corresponds in the two gauges to two different values of the time coordinate $x^0(\mu)$ in the synchronous gauge and $x^0(\mu)$ in the longitudinal one. Using the transformation laws for $B$ and $E$

$$B(\mu) = B(\mu) + a \theta_k \theta_k \eta_{(1)}; \quad E(\mu) = E(\mu) + a \theta_k \theta_k \eta_{(1)}; \quad (14)$$

(see [23] for more details) and taking into account that $B$ is zero in both gauges and $E$ is zero in the longitudinal gauge, we obtain

$$x^0 = x^0(\mu) \quad (15)$$

Using equations (9), (13a) and (15) we end the following transformation law for the determinant of the spatial part of the metric

$$P g_{(1)}(x^0(\mu)) = P g_{(s)}(x^0(\mu)) \text{d} P = \theta_k \theta_k \eta_{(1)}(\mu) \quad (16)$$

Taking the divergence of (13b) and multiplying by the scale factor we obtain

$$a u^0_{\mu(1)}(\mu) + a u^0_{\mu(1)}(\mu) + a \theta_k \theta_k \eta_{(1)}(\mu) = \theta_k \theta_k \eta_{(1)}(\mu) \quad (17)$$

After integration over the time coordinate in (10) and asymptotic expansion of the exponent, the second term on the right-hand side of (11) cancels the analogous term in (12), so that $r(\mu) = r(\mu)$. In other words, is invariant under the gauge transformation. Three-dimensional scalars like the particle number density are gauge invariant as well: $r(\mu) = r(\mu)$. Together with the gauge invariance of $\eta$, this implies the gauge invariance of $\eta$.

Another important gauge invariant three-dimensional scalar is the energy density

$$T^0_0 = R \frac{g}{\mu} \frac{P}{\mu} [\xi(E \mu)] \text{d} P \quad (18)$$

A scan be shown by a direct calculation, for a gas of massless particles distributed according to the Boltzmann distribution the leading contribution to the energy density due to a small macroscopic velocity $u$ is proportional to $u^2$, i.e. is of second order and can be neglected. Thus $\dot{\eta} = \text{const}$, and the temperature $T$ (as well as the inverse tem perature $z$) is gauge invariant.

Therefore the left-hand side of (12) is gauge invariant since the derivative of one invariant quantity with respect to another invariant quantity is also invariant.

On the right-hand side of (12) the integral of the collision term $s$ over the phase space is also invariant under
the gauge transformation. Finally, since
\[ \frac{p}{g_{00}} \frac{\partial z}{\partial t} = \frac{\partial z}{\partial t} \quad (19) \]
and the (inverse) temperature \( z \) as well as the proper time \( t \) are gauge invariant, the ratio (19) is also invariant. This completes our proof of the invariance of the integral Boltzmann equation under the gauge transformation (13).

Instead of the transformation between synchronous and longitudinal gauge, we could have considered a transformation between two different gauges which fulfill \( B = 0 \). The calculation would differ only in \( E \) being now different from zero in both gauges and appearing also on the left-hand side of equations (15) and (16), which however does not change the conclusion concerning the invariance of (12). Therefore, we may conclude that equation (12) is invariant not only under the transformation between longitudinal and synchronous gauge, but under all gauge transformations that preserve the gauge condition \( B = 0 \).

### III. INHOMOGENEOUS LEPTOGENESIS

To calculate the lepton asymmetry generated in the decays of the heavy Majorana neutrino one has to solve a coupled system of Boltzmann equations for the heavy neutrino and lepton number densities.

To be able to perform this calculation analytically we neglect the contribution of the heavy neutrinos to the energy density of the universe. This is justified by the smallness of the associated number of effective massless degrees of freedom as compared to that of all the SM species. The two-body scattering processes and the a-priori neglected for simplicity. In the simplest scenario of inhomogeneous perturbations in the gas of the SM species are suppressed and we also neglect them. In particular, this implies that the same for leptons and photons so that \( N_\ell = n_\ell = 1 \).

The possible deviation of the macroscopic velocity of the heavy neutrino gas from that of leptons (i.e., velocity perturbation in the right-handed neutrino compton) is parametrized by \( x_\ell = 1 - \frac{\overline{u}_\ell}{u} \).

A. Approximate analytical solution of the system of Boltzmann equations

The collision term is determined by the coupling of the Majorana neutrino to leptons and the Higgs
\[ L = N (\nu^\dagger \nu) \frac{1}{2} N^T N + h \nu \cdot \nu \quad (20) \]
where \( \nu \) denotes the leptons, \( \nu = i \nu^L \) is the charge conjugate Higgs doublet, and \( N \) are the components of physical Majorana neutrino \( \nu_\ell = \frac{1}{\sqrt{2}} (N + N^C) \).

Under the usual assumption that the phase-space distribution function of the Majorana neutrino is proportional to the equilibrium one, the contribution of the decay (1) \( \nu \) and the inverse decay \( \nu \) processes to the lepton asymmetry reads
\[ Z \frac{\partial}{\partial E} \frac{\partial}{\partial p} = h \nu \cdot \nu \]

where \( \nu \) is the usual CP asymmetry parameter and \( h \nu \cdot \nu \) is the thermally averaged heavy neutrino decay width.

Integrating over the equilibrium distribution function and neglecting a second-order contribution due to the small macroscopic velocity we find
\[ h \nu \cdot \nu = \frac{K_1(z)}{K_2(z)} \quad (22) \]

where \( K_1 \) and \( K_2 \) are the modified Bessel functions. The equilibrium number densities are obtained by integration of the corresponding Maxwell-Boltzmann distribution functions over the phase space
\[ n_{\text{eq}} = N^3 z^2 K_2(z); \quad n_{\text{eq}} = 4N T \frac{T^3}{\pi} \quad (23) \]

where \( N = 3 \) is the number of generations. One should keep in mind that \( T \) refers to leptons and the Higgs; the right-handed neutrino is out of equilibrium and does not have a definite temperature.

The same processes also contribute to the right-hand side of the Boltzmann equation for the Majorana number density (24)
\[ Z \frac{\partial}{\partial E} \frac{\partial}{\partial p} = h \nu \cdot \nu \quad (24) \]

In the homogeneous and isotropic universe dominated by radiation (see 17) for more details
\[ = \frac{p}{g} = \frac{a^3}{T_0^3} \quad \frac{p_{g_{00}}}{z} = \frac{x_0}{H} \quad (25) \]

1 Perturbations of the space-time metric may in principle lead to a change of decay widths and cross sections of the scattering processes. These effects, however, are not considered here. Following common practice we assume that the widths and cross sections are given by the same expressions as those in vacuum. Then the perturbations only affect the thermally averaged decay widths and scattering cross sections through the modification of the temperature and the related modified cation of the equilibrium phase-space distribution functions.

2 In the gas rest frame the thermally averaged decay width depends only on temperature. A time Lorentz boost to the initial reference frame the decay width acquires the Lorentz factor, which differs from unity only by a second order term.
where \((z_0) \equiv T_0\) is the (inverse) background temperature and \(H\) is value of the Hubble parameter at \(r = 0\) and \(r = r_0\) is the density of the lightest Majorana neutrino in the inhomogeneous universe. We tentatively write

\[
\frac{1}{T} \frac{\partial}{\partial r} + \frac{r}{z} = \frac{z}{H} (1 + r_0) \tag{26}
\]

where \(r_0\) and \(r_0\) are functions of order gauge (invariant) and in what follows we will use \(r\) and \(r\) for the heavy neutrino and SM species, respectively. Introducing \(z = \frac{r}{r_0}\) and

\[
d(z) = \frac{K_1(z)}{K_2(z)}; \quad L(z) = \frac{z^2}{4N} K_2(z) \tag{27}
\]

we obtain the following system of Boltzmann equations for the lepton asymmetry and Majorana neutrino number density

\[
0 = z (1 + r) \frac{\partial \phi_{eq}}{\partial z} \tag{28a}
\]

\[
0 = z (1 + r_0) [\phi_{eq}(0) - z_0^2 K_2(z)] \tag{28b}
\]

where the relation \(r_0 = \frac{r}{r_0}\) has been used. If \(r\) and \(r_0\) vanish, the resulting system coincides with that in the homogeneous universe and the generated asymmetry depends only on \(z_0\) and \(\theta\).

In the weak washout regime \(1\) the deviation from equilibrium is large and washout processes play a role, so that \(0 = \phi_{eq}(0)\). Together with the initial conditions \(0 = L(0) = 0\) this gives upon integration by parts and use of the zero (order solution of \(28a\), \(0 = (0) \exp(\hat{\tau} = 0) - \hat{\tau} = \hat{\tau}(0)\))

\[
Z = 0 \rightarrow 0 = \frac{z}{L} + \frac{1}{L} \frac{1}{r_0} \exp(\hat{\tau} = 2) \tag{29}
\]

where the unperturbed value of the generated asymmetry in the weak washout regime is given by

\[
0 = \phi_{eq}(0) = \phi_{eq}(0) = \frac{z}{L}(1 + r_0) \tag{30}
\]

In the strong washout regime \(1\) the deviation from equilibrium is negligible, so that the Majorana asymmetry is independent of the initial conditions and determined by the dynamics of leptogenesis. In this regime the density of a Majorana neutrino closely tracks its equilibrium value, which in place of \(0 = \phi_{eq}(0)\). Substitution of \(28a\) into \(28b\) then gives

\[
0 = \phi_{eq}(0) = \frac{z}{L}(1 + r_0) \tag{31}
\]

where \(z = 0\) and \(z = z_0\) is the unperturbed value of the generated asymmetry in the strong washout regime.

The form of a solution of this equation satisfying the initial conditions \(0 = L(0) = 0\) reads

\[
L = \frac{z}{L} (1 + r_0) \phi_{eq}(0) \exp(\hat{\tau} = 2) \tag{28b}
\]

\[
0 = \phi_{eq}(0) - \hat{\tau} = \frac{z}{L} \exp(\hat{\tau} = 2) \tag{32}
\]

For \(z = 1\) one can use the large (argument) asymptotic solution of the Bessel functions \(K_1\) and \(K_2\), so that approximately

\[
\phi_{eq}(z) \approx \frac{z}{L} \exp(\hat{\tau} = 2) \tag{33}
\]

The arguments of the exponents in \(32\) and \(33\) combine to a function which has a sharp peak at \(z = z_0\), where \(z_0\) is the solution of

\[
z_0 = z_0(1 + r_0) = 1 \tag{34}
\]

Consequently one can apply the method of steepest descent to estimate the asymptotic value of this integral. Approximating \(L\) by its large (argument) asymptotic solution and keeping only the terms of highest order in \(z_0\) we obtain

\[
L = (1 + r_0) z_0^2 \tag{35a}
\]

\[
L = 1 + 2 \phi_{eq}(z_0) \frac{z_0}{r_0} \tag{35b}
\]

A deviation of \(r_0\) from zero leads to a deviation of \(z_0\) from its unperturbed value. Using \(34\) one can show that the shift is given by \(z_0 - \frac{z_0}{r_0} = z_0(z)\), where \(z_0(z)\) denotes the value of the freezeout temperature in the \(r_0 = 0\) case.

Using equations \(34\) and \(35\) we get for the asymptotic value of the asymmetry

\[
L = (1 + r_0) z_0^2 \tag{36}
\]

where the unperturbed value of the generated asymmetry in the strong washout regime is given by

\[
L = 0 = \frac{z_0^2}{z_0} N \left( \frac{P}{2} \frac{2}{z_0} \right) \exp(1) \tag{37}
\]

Despite its simplicity, for \(\beta \approx 10\) the analytical solution \(28\) deviates from the exact numerical solution of \(28\) by only a few percent and correctly describes the dependence of the asymmetry on \(r\) and \(r_0\). For large the inverse freezeout temperature \(z_0 \approx 1\) and the term proportional to \(z_0^{-1}\) in the denominator can be neglected.

\[\text{The gauge invariance of } r \text{ and } r_0 \text{ follows from the gauge invariance of the (inverse) temperature and of } \frac{T}{r_0}.\]
B. The baryon to photon ratio

To complete the analysis we have to evaluate \( r \) and \( r_b \). Introducing the dimensionless temperature perturbation \( \frac{1}{T_0} \), one can relate \( z \) to its background value \( z = z_0 (1 + 1) \). Using the known dependence of \( z_0 \) on the time coordinate in the radiation (dominated universe, \( z_0 = H x^0 / a \)), and the resulting relation \( z \), \( z_0 \), \( H \) we obtain for the derivative of \( z \)

\[
\frac{dz}{dt} \left( \frac{1}{g_0} \right) = \frac{1}{g_0} \left( \frac{1}{H} \right) \frac{1}{z_0} \left( \frac{1}{H} \right) \frac{1}{g_0} \left( \frac{1}{H} \right) = \frac{1}{g_0} \left( \frac{1}{H} \right) \frac{1}{g_0} \left( \frac{1}{H} \right) ; \tag{38}
\]

which implies

\[
r_b = - 2 + \frac{H}{1} = \tag{39}
\]

Expanding the exponent in \( R \) and neglecting second-order terms one can write in the form

\[
a^3 (x_0) = 1 + + \text{R} + \text{a} \mu_i \text{d}x^0 ; \tag{40}
\]

where the scale factor is related to the background temperature by \( a^3 / T_0 = \). Consequently

\[
r = 3 + + \text{R} + \text{a} \mu_i \text{d}x^0 ; \tag{41}
\]

Since \( r \) and \( r_b \) are gauge invariant, it is sufficient to evaluate them in one particular gauge. In the longitudinal gauge solution of the Einstein equations for the Fourier componets of \( r \) and in the radiation (dominated universe reads \( [17] \)

\[
k = C_1 \left( \begin{array}{c}
\sin x \\
\cos x
\end{array} \right) \left( \begin{array}{c}
\cos x \\
\sin x
\end{array} \right) + C_2 \left( \begin{array}{c}
\cos x \\
\sin x
\end{array} \right) + \sin x \left( \begin{array}{c}
\cos x \\
\sin x
\end{array} \right) \tag{42a}
\]

\[
k = C_1 \left( \begin{array}{c}
\frac{2}{x^2} \\
\frac{1}{x}
\end{array} \right) \sin x \left( \begin{array}{c}
\cos x \\
\sin x
\end{array} \right) + C_2 \left( \begin{array}{c}
\frac{1}{x^2} \\
\frac{1}{x}
\end{array} \right) \cos x \left( \begin{array}{c}
\cos x \\
\sin x
\end{array} \right) \tag{42b}
\]

where \( x, \frac{2}{x^2} \). The initial conditions are specified by \( C_1 \) and \( C_2 \), which are functions of \( k \). The divergence of the macroscopic fluid velocity \( u_\mu \) can be calculated using the Einstein equation for the diagonal componets of the Riemann tensor. In the absence of an isotropic stress, \( \epsilon \), and these simplify to \( (\alpha^-) = 4 \text{G}a^2 (\epsilon_\alpha) + p_{\alpha} \). After use of the Friedmann equation, \( 3H^2 = \frac{8 \text{G}a^2}{c^2} \), and some algebra we obtain for the corresponding Fourier componets in the radiation (dominated universe

\[
k = \frac{k^2}{2a} (\alpha^-) ; \tag{43}
\]

Trading the integration with respect to the time coordinate for the integration with respect to \( k \) and taking into account the equality we find for the Fourier transform of \( r^5 \)

\[
r_k = 3 = \frac{3 \gamma}{2} \left( \frac{3}{2} \right) (k) dx = 0 ; \tag{44}
\]

Using the relation \( r \frac{dx}{dx} = \frac{3}{2} \gamma \frac{3}{2} \gamma \), we obtain a very simple expression for the Fourier transform of \( r_b \)

\[
r_b = k + + \frac{3}{2} \gamma \frac{3}{2} \gamma = \frac{3}{2} \gamma \frac{3}{2} \gamma C_1 \sin x + C_2 \cos x ; \tag{45}
\]

The lepton to photon number ratio \( r = \frac{L}{L_0} \), can now be easily read off from \( (29) \) and \( (38) \). The quantity of interest is the departure of the asymmetry from its background value, \( r \frac{L}{L_0} = 1 \). Since the baryon asymmetry is linearly related to the lepton number \( r \) also characterizes the baryon isocurvature perturbations. Neglecting the term proportional to \( z \) in the denominator of \( (29) \), we find in the strong washout regime

\[
r = r_0 (z_0) \left( \frac{z}{z_0} \right) = \frac{1}{2} \frac{r_0}{z_0} (z_0) ; \tag{46}
\]

The calculation of the CMB anisotropies is performed in momentum space, so that one is interested in the Fourier components of \( r \). The Fourier transform must be evaluated at the inverse freezeout temperature \( z_f \); it corresponds to \( x = z_f X \), where \( X = \frac{2}{\gamma} \). The value of \( x \) takes at \( z = 1 \), and \( R \), \( H \), \( M_\gamma \), \( M_\gamma \), \( M_\gamma \), \( M_\gamma \) is the Hubble scale at this stage. The derivative of \( (44) \) with respect to the inverse temperature can be obtained upon use of the zero-order relation \( R = \frac{z}{z_0} \). Using the introduced notation we find for the Fourier transform of \( r \) in the strong washout regime

\[
r_k = \frac{X}{\gamma} \frac{z_0}{\gamma} + \frac{1}{2} (2C_1 z_f + C_2 \sin x z_f \gamma + \frac{1}{2} (2C_2 z_f + C_1) \cos x z_f ; \tag{47}
\]

In this regime the heavy neutrinos are tightly coupled to the SM species and it is natural to expect that \( r \) vanishes. The typical size of the perturbations is given by the Hubble radius \( R \). On larger scales \( r_k \) is suppressed

\[\text{Equation (43) implies that for the photons } r_k = 0 = 1 \text{ is constant in the early universe, just as expected. Since photons are in equilibrium in the early universe, the right-hand side of the Boltzmann equation for photons vanishes and is conserved.}

\[\text{A calculation using the solution of the Einstein equations for small perturbations in the synchronous gauge given in [23] leads to the same expressions for } r \text{ and } r_b \text{ as the gauge invariance of the introduced functions.}

\[\text{Since the contribution of the heavy neutrinos to the energy density is neglected, the baryon-to-photon ratio is related to the baryon-to-entropy ratio by a constant factor at this stage of the universe's evolution. Later, as the SM species decouple as they become massive, the baryon-to-entropy ratio remains constant, whereas the baryon-to-photon ratio changes. This change is absorbed into the definition of the background value of the asymmetry and does not modify the expressions for } r_k .\]
by the overall factor $X$, which becomes small on superhorizon scales $r_\perp = \sqrt{2} X (2C_2 z_\perp + C_1)$ and vanishes as $X \to 0$.

From (43) it follows that in the weak washout regime
\[ r = \frac{\theta}{y_\tau} r_\perp \exp\left( -\frac{x^2}{2} \right) dx; \quad (48) \]

where we have used the relation $x = zX$. That is, a non-zero $r$ is generated in this regime only if the velocity of the right-handed neutrino deviates from that of the SM species. The typical scale and amplitude of $r_{\perp}$ are model-dependent. Nevertheless, one can make a plausible guess about these quantities: if perturbations in the SM and heavy neutrino components are created by the same mechanism, then the typical amplitude and scale of $r_{\perp}$ cannot exceed those of the velocity perturbation of the SM species. Since we are interested in large scale perturbations, which correspond to small $X$, it is sufficient to know the behavior of $r_{\perp}$ in the vicinity of $x = 0$.

\[ X \sim a_0 x^0; \quad a_n \sim O (C_{1,2}); \quad (49) \]

If, for example, $u$ vanishes in the longitudinal coordinates$^8$, then as follows from (43) $a_1 = 3C_2, a_0 = \frac{1}{2} C_1, a_2 = \frac{1}{4} C_1, \ldots$, whereas if $u$ vanishes in synchronous coordinates, then $a_1 = \frac{1}{2} C_2, a_2 = \frac{1}{4} C_1, \ldots$ (see Eq. (15) in [23].) To integrate the term with negative $n$ we cut the integral at some $x_{\min}$ such that $a_n x_{\min}^n < 1$ to ensure the applicability of the perturbative treatment. We first assume that only very large scales $X \sim x_{\min}$. Then

\[ r_{\perp} = a_1 \frac{1}{2} X + O (X^2); \quad (50) \]

That is, in the weak washout regime $r_{\perp}$ is also suppressed on large scales.

**C. BBN and CMB**

In the radiation-dominated universe the horizon size grows much faster than the scale factor, and consequently the generated perturbations are not protected from smoothing by baryon dilution at later stages of the universe's evolution.

Let us first consider the strong washout regime. Relation (44) holds for arbitrary mass of the Majorana neutrino. For the right-handed neutrino mass $M_1 \sim 10^9 \text{GeV}$, scales of the order of $R$ at the time of leptogenesis correspond to (roughly speaking) $10^5 \text{m}$ at neutrino decoupling. This is much smaller than the baryon diffusion length $\sim 200 \text{m}$ at this stage. Therefore, in this case

the perturbations of the baryon to photon ratio are completely smoothed out before nucleosynthesis starts. In the electroweak (scale resonant leptogenesis scenario)

the Hubble scale at the time of leptogenesis corresponds to (roughly speaking) $10 \text{km}$ at $0.1 \text{MeV}$. At the latter temperature, which corresponds to the beginning of nucleosynthesis, the neutron diffusion length is $200 \text{km}$. In other words, the baryon perturbations are not smoothed out on scales which correspond to $X = 0$ at the time of leptogenesis. Given the typical size of the integration constants $C_{1,2} \sim 10^{-5}$, the amplitude of the perturbations not washed out by baryon diffusion is so small that a correct nucleosynthesis in an observable way.

After the end of nucleosynthesis and before the beginning of recombination there are no neutral baryons and the diffusion length substantially decreases. Thus the baryon isocurvature perturbations which have not been smoothed out survive till recombination (the time of CMB formation). At this stage small scale perturbations on the photon gas undergo a mechanism called diffusion damping or Silk damping [27, 28]. The photons diffuse from regions with higher density to lower density regions and thereby effectively smooth out baryon inhomogeneities due to large-scale free paths. This damping of acoustic oscillations by a factor

\[ Z_{\text{diff}} \sim \exp \left( -\frac{M_c}{M} \right); \quad (51) \]

where $Z$ is the damping rate, $t_0$ the present time and $M_c$ is called the critical mass that can only be obtained approximately from the integral over the damping rate.

For a radiation-dominated universe during the phase of acoustic oscillations, one obtains

\[ M_c \sim 8 \times 10^7 (\sigma T_h^2)^{-1} \text{MeV} \quad (52) \]

with density parameter $\Omega_0$ and rescaled Hubble parameter $T_0$ evaluated at the present time $t_0$ and $M$ denoting the solar mass. Sufficient damping then occurs for $M_c \sim M$ of the order of 10 or larger. Translated into length scales, this means that all scales

\[ D \sim 3 \times 10^8 \text{m} \quad (53) \]

are acted upon by Silk damping at $T \sim 10 \text{eV}$, which roughly corresponds to the temperature at recombination, and only perturbations on scales larger than that can survive. For the right-handed neutrino mass $M_1 \sim 10^9 \text{GeV}$, scales of the order of $R$ at the time of leptogenesis correspond to scales of the order of $10 \text{m}$ at recombination. This is obviously smaller than the damping scale $\sim M$ by so many orders of magnitude that no observable in print on the CMB can be produced. Turning the argument around, we can calculate the mass scale $M_1$ that would be necessary to obtain perturbations on large enough scales to prevent them from being smoothed out by Silk damping, taking into account that the scale $R$ scales as $T^2$ in a radiation-dominated universe. The

---

$^8$ The analysis performed in [23] in longitudinal gauge demonstrates that velocity perturbation of the heavy dark matter particles are small compared to those of the massless species.
result is very disappointing; one would need a mass scale of \( M_1 \) = 100 eV which is far below the scale where the sphalerons are in thermal equilibrium and can convert a lepton asymmetry into a baryon asymmetry. Therefore we conclude that in the strong washout regime, the baryon inhomogeneities come from the spatial fluctuation of the energy density and leptogenesis cannot be a mechanism of the electroweak scale. The typical scale of the perturbations at the time of leptogenesis is set by the Hubble scale \( H \) in both regimes. The amplitude is inversely proportional to the scale.

The generated perturbations are smoothened by baryon diusion at the later stages of the universe's evolution. The scale of the generated perturbations is comp
dable to the neutrino diusion length at the beginning of BBN only if the right-handed neutrino is as light as in the electroweak (scale resonant leptogenesis scenario). However even in this extreme case the generated perturbations are smoothened out by the Silk damping at the recombination. For this reason the in uence of the baryon inhomogeneities coming from the spatial fluctuation of the energy density of leptogenesis on BBN and the cmb is unobservably small.

IV. SUMMARY AND CONCLUSIONS

In this short paper we have investigated the in uence of the primordial perturbations of the energy density and metric on the energy density and metric of the early universe. To perform the analysis we have derived an integral form of the Boltzmann equation for a gauge invariant combination of particle number density, the macroscopic udi velocity and space-time metric. In the absence of the collision term \( s \) is conserved to linear approximation and replaces the particle number density per comoving volume in the inhomogeneous universe.

Using the integral form of the Boltzmann equation approximate analytical solutions for the lepton asymmetry in the weak and strong washout regimes have been found.

In the strong washout regime the generated baryon isocurvature perturbations are correlated with the perturbations of the energy density and metric. In the weak washout regime the solution deviates from the background one only in the presence of the heavy neutrino velocity perturbation \( \tau \). The typical scale of the perturbations at the time of leptogenesis is set by the Hubble scale \( H \) in both regimes. The amplitude is inversely proportional to the scale.

The generated perturbations are smoothened by baryon diusion at the later stages of the universe's evolution. The scale of the generated perturbations is comparable to the neutrino diusion length at the beginning of BBN only if the right-handed neutrino is as light as in the electroweak (scale resonant leptogenesis scenario). However even in this extreme case the generated perturbations are smoothened out by the Silk damping at the recombination. For this reason the in uence of the baryon inhomogeneities coming from the spatial fluctuation of the energy density of leptogenesis on BBN and the cmb is unobservably small.

Acknowledgements

The authors are grateful to Prof. E. Paschos for drawing their attention to the problem of leptogenesis in an inhomogeneous universe and numerous discussions, to Prof. D. Schwarz for his kind help and to Dr. T. Underwood for careful reading of the manuscript.
