April 17, 2013

ABSTRACT

Context. The contrast of granulation is an important quantity characterizing solar surface convection.

Aims. We compare the intensity contrast at 630 nm, observed using the Spectro-Polarimeter (SP) aboard the Hinode satellite, with the 3D radiative MHD simulations of Vogler & Schussler (2007).

Methods. A synthetic image from the simulation is degraded using a theoretical point-spread function of the optical system, and by considering other instrumental effects.

Results. The telescope aperture and the obscuration by the secondary mirror and its attachment spider, reduces the simulated contrast from 14.4% to 8.5%. A slight effective defocus of the instrument brings the simulated contrast down to 7.5%, close to the observed value of 7.0%.

Conclusions. A proper consideration of the effects of the optical system and a slight defocus, lead to sufficient degradation of the synthetic image from the MHD simulation, such that the contrast reaches almost the observed value. The remaining small discrepancy can be accounted for stray light and slight imperfections of the instrument, which are difficult to model. Hence, Hinode SP data are consistent with a granulation contrast which is predicted by 3D radiative MHD simulations.

Key words. Sun: granulation, Sun: photosphere

1. Introduction

The root-mean-square of the normalized continuum intensity fluctuations, within an area on the solar disk, is determined mainly by the intensity variation between the bright granules and the darker intergranular lanes, and thus is usually referred to as the granulation contrast. It is a key property of solar surface convection because it is connected with the temperature difference between rising (granules) and descending gas masses (intergranules), and thus related to the opacity of the convective energy transport.

Reliable measurements of the granulation contrast are notoriously difficult, since the observed contrast depends significantly from in age degradation by the optical system and, most importantly in the case of ground-based telescopes, by seeing and stray light effects due to the terrestrial atmosphere. To deduce the "true granulation contrast" from measurements, we need to deconvolve the observed images by considering the modulation transfer through the optical setup (telescope, instrument, detector, etc.), in addition to the atmospheric effects. The quantitative effects of the latter are poorly understood and it is therefore unsurprising that the reconstructed values of the granulation contrast, documented in the literature, cover a broad range (see, e.g., Table 2 in Sanchez Cubere et al. (2003). This remains true even if additional constraints, such as measurements of the intensity profile across the solar limb during a partial eclipse, are used to derive the effective point-spread function (e.g., Lery 1971; Deubner & Mattig 1975; Nordlund 1984; Sanchez Cubere et al. 2003).

In the case of balloon-borne stratospheric observations, the influence of the atmosphere is negligible. Even under these conditions, however, the scatter of the reconstructed contrast values is large (Balogh & Schwarzschild 1961; Pardyuk et al. 1974; A. Lagg et al. 1977; A. Lagg et al. 1983; K. Funayama & M. Matsumoto 1973; Schmitt et al. 1973; W. Tom Meier et al. 1981), presumably because the proper consideration of the instrumental effects is nontrivial (Durrant et al. 1983).

Although the range of contrast values derived from observations is quite wide, the values predicted by 3D radiative HD/MHD simulations are significantly higher (e.g., Stein & Nordlund 2000; Vogler et al. 2007; W. Edlen & Bohm 2007). This is unsurprising, since the horizontal resolution of such simulations (10(40 km) is far better than what can be achieved observationally at present. To compare the observed contrast values with predictions from simulations, the synthetic images derived from simulations must be degraded in the same way as the observations, taking into account the effects of the optical system and, in the case of ground-based telescopes, the terrestrial atmosphere. This procedure is prone to the same uncertainties as the deconvolution of observations; the result depends strongly on assumptions about the nature of atmospheric seeing and stray light (Nordlund 1984; Schussler et al. 2003; Rybak et al. 2008) and we are unable
to infer if the simulation predictions are consistent with observations, or otherwise. However, the good agreement between observed and simulated spatially averaged spectral line bisectors indicates that the simulated intensity contrasts are probably close to actual values [Spalding et al. 2004].

A new era has begun with the launch of the 50-cm Solar Optical Telescope (SO T, Tanaka et al. 2003) on the Hinode satellite (Kosugi et al. 2007). The good performance and low straylight level of the spectro-polarimeter (SP, Lites et al. 2003) and complete absence of atm ospheric effects, enable a firm and reliable determination of the granulation contrast at 630 nm, the wavelength at which the SP operates. In this Letter, we compare the intensity contrast of a Hinode SP continuum map of the quiet Sun with predictions of M HD simulation.

2. Observations and simulation data

We det emine the observed contrast from a map of the continuum intensity at 630 nm wavelength obtained on Jan. 16, 2007 (12:01:00 UT), using the scan mode of the Hinode SP with an exposure time of 48 s per slit position. The map covers a field of 16° 16° on the disk center. The slit width, the sampling step size, and the CCD pixel pitch all correspond to 016°. The data were reduced using standard routines that correct for various instrum ental effects (Lites et al. 2007). A first reduction, we nd an image contrast of the continuum intensity of 7.0%.

The 3D M HD simulation snapshot that we consider represents the saturated (statistically stationary) state of the dynamical run C of Vogler & Schussler (2003). The computational box contains 648 x 648 x 140 cells; it corresponds to a physical size on the Sun of 486 x 486 Mm² in the horizontal and 14 Mm in the vertical direction, the latter ranging from about 900 km below to 500 km above continuum optical depth unity at 630 nm ( t=1). The simulation has been run with non-grey radiative transfer using the MURaM code [Vogler 2003; Vogler et al. 2005]. With a horizontal grid-cell size of 7.5 km, this simulation had one of the highest resolutions achieved so far. The snapshot that we use, has an average unsigned vertical magnetic field of about 7 G at t=0,1, which we consider as a reasonable representation of the quiet Sun's coronal magnetic field. The corresponding original (unsmoothed) continuum image at 630 nm shows an image contrast (standard deviation divided by mean value) of 14.4%. The particular choice of snapshot was not critical for the results presented here. Considering a number of other snapshots and simulations of diff erent spatial resolutions or amounts of magnetic flux in the simulation box, we find contrast values that were typically between 14% and 15%

3. Modeling of the system PSF

The difference between the observed and original contrast of the simulation amounts to more than a factor of two (7.0% vs. 14.4%). Since there is no atm ospheric distortion of the image, we investigate whether instrument effects alone account for this significant degradation.

The intrinsic resolution of the simulated images considered here (equivalent to 0016° pixel size) is considerably better than the resolution of the 50-cm Hinode SO T; the degradation of the synthetic image based on the simulation result can therefore be modeled by applying an effective point-spread function (PSF). We convolved our simulated intensity maps in the 2D spatial domain with different PSFs, which represented a m one and more realistic optical system. To this end, we modeled the telescope and the transfer optical path down to the spectrograph entrance slit using the commercial optical design software ZEMAX. While the telescope was modeled with the nominal SO T surface param eters, the transfer (recouping) path was modeled in paraxial approximation, which, however, has no influence on the final results of our calculations. ZEMAX calculates the PSF as the Fourier transform of the wavefront of the exit pupil of the system.

We describe the contrast degradation by the optical system using the Modulation Transfer Function (MTF), which is the Fourier transform of the point-spread function. In this way, the various e effects can be considered step by step, as indicated below. Figure 1 shows the corresponding change of the system MTF.

Telescope aperture: The Hinode SO T is an f=9:1 G regory system with an aperture of 50 cm, which corresponds to a cut-off at 1=026°. Higher spatial wave numbers are not transmitted by the system, while low to intermediate wave num bers are transmitted with relatively high contrast.

Central obscuration and spider: Important contributions to the contrast degradation are the central obscuration of the telescope by the secondary mirror, which produces a linear obscuration of 0.34 = 172 cm = 50 cm, and the diaphragm by the three spider elements, which are of 4 cm with each, holding the secondary. The effect of the central obscuration is that the highest spatial wave numbers are largely unaffected, while the intermediate wave numbers are significantly dampened. The spider structure adds to this damping.

Spatial sampling: Since the data considered here are obtained using the spectro-polarimeter, we have to consider the sampling and integration effects of the slit and the CCD detector. The sampling and the integration effects of the detector are approximated by powers of sinc functions [Boreman et al. 2001].

Defocus: Low-order optical aberrations damp the MTF at low spatial wave numbers. Since the Hinode Focal Plane Package (FPP) is a complex system, it is out of the scope of this Letter to model in detail all relevant contributions from optical, opto-mechanical, and electronic parts of the system. We therefore consider only the effect of a defocus in the plane of the SP slit. It turns out that a small amount of defocus can reduce significantly the intensity contrast, while leaving the small-scale resolution of the system unchanged. The focus of the Hinode science instruments is controlled by means of a coarse focus mechanism that can be shifted in a range of 25 mm with a step of 0.17 mm.

In addition, we investigated the effect of the (lossy) JPEG compression which was applied to the images. The change of the small contrast turned out to be negligible, even for high compression factors.

4. Degradation of the simulation data

To compare with the Hinode result, we convolved the intensity maps calculated from the simulation with the detector PSFs resulting from modeling the Hinode SOT as described in the previous section. After convolution, the degraded images were binned to represent the samling and integration effects of the nine slit width, step size of the spatial sampling, and the pixel size.

Table 1. Values of the sm intensity contrast after applying the FPs corresponding to the MTFs shown in Fig.4.

Figure 2 shows the evolution of the histogram of intensity values in the simulation image as the various effects of the optical system are introduced. The small contrast values for the various steps are listed in Table 1. The basic telescope effect (primary aperture, obscuration, and spider) reduces the small contrast to 8.7%, presumable since the small all-scale intensity structure in the intergranular lanes is lost. There is almost no further contrast degradation due to sampling and rebinning (CCD), which indicates that the remaining contrast is determined mainly by spatial scales that are significantly larger than the critical sample limit of the detector pattern. Once the detailed structure in the granular lanes is no longer resolved, the contrast is dominated by the intensity differences between the granules and the average intensity of the intergranular lanes, which is almost unaffected by the integrating effect of the detector pixels. Similar values of the contrast reduction up to this step were obtained by Orozco Suarez et al. (2007).

The difference between the small contrast degraded so far (8.5%) and the observed contrast (7.0%) is still significant. Another factor that contributes to contrast degradation is a slight defocus of the SP, which affects mainly the low to intermediate spatial wave numbers. We have no direct information about the amount of defocus for the dataset considered here; we, however, obtained empirical evidence about the effect of defocus on the intensity contrast using a number of SP datasets for different focus positions, taken only an hour earlier than the map analyzed here. Apart from the exposure time of 1.5 s per slit position and the small size of the maps, all other observational parameters are the same. For every focus position, a map that covers a field of 320 x 820 was generated. The corresponding contrast values given in Fig.5 con rm the rather sensitive dependence on focus position. The curve also shows the dependence of the contrast of the simulation image on the defocus value. The large observational maps with a contrast of 7.0% (indicated by the asterisk) was taken with a defocus of 0-9 steps (1.36 mm to 1.53 mm) from the optimal position in Fig.5.

The degraded simulation image corresponding to about this defocus value (1.5 mm) has a contrast of 7.5%.

As an illustration of the importance of defocus, Fig.5 shows the evolution of the histogram of intensity values in the simulation image from the simulation left panel, the periodic simulation box is drawn fourfold for the sake of better visibility and the final degraded image (middle). A subset of the observational map of the same size is shown in the right panel, using the same gray scale.

The remaining deviation of 0.5% from the observed value of about 7% can be attributed to various degrading factors that are not included in our analysis. These include the effects of straylight, of all other low-order optical aberrations apart from defocus, and of the
Fig. 4. Continuum images at 630 nm from the simulation snapshot with original resolution (left) and after degrading (middle), in comparison with a detail of the observed H node/SP map of the same size (right). The periodic simulation box is shown fourfold for better visibility.

Fig. 3. Intensity contrast as a function of telescope defocus. Shown are results for a SP data set used taken on Jan. 16, 2007, 10:54:14 (diamonds) and the contrast values for the degraded simulation image (crosses). The value for the large map used to compare with the simulation is indicated by the asterisk, assuming that the location of the optimal focus was the same as for the other dataset. This also gives an indication of the observational uncertainty.

Read-out electronics (such as transfer electronics and pixel-to-pixel crosstalk), which reduce the contrast, but are difficult to model reliably. To illustrate the extreme sensitivity of the granulation contrast to low-order aberrations and straylight we calculated, as an example, for ZEMAX the effect of astigmatism and coma, which were equally distributed in such a way that the total system showed an rms wave-front error of 0.044 wavelengths. This corresponds to the numbers given by Suenatsu et al. (2008) and represents a system with a remarkable Strehl ratio of 0.93. This small effect is nevertheless sufficient to reduce further the contrast from 8.5% to 8.1% in optimal focus position. If no further degrading effects are present, a straylight level of only 4.7% would be sufficient to bring the contrast down to the observed value of 7.8% (for optimal focus), and to 7.0% for the presumptive defocus value of the dataset studied here, respectively.

5. Conclusion

We find that consideration of the basic optical properties of the H node SO T/SP system and a slight defocus are sufficient to bring the degraded contrast of a 3D radiative MHD simulation and the observed continuum contrast at 630 nm into agreement. The remaining discrepancy can be attributed to the combined, minor effects of straylight, other low-order optical aberrations, and instrument electronics. Hence, H node SP data are consistent with a granulation contrast at 630 nm of 14–15%, as predicted by the simulations.

Acknowledgments. H node is a Japanese mission developed and launched by ISAS/JAXA, with NAOJ as domestic partner and NASA and STFC (UK) as international partners. It is operated by these agencies in cooperation with ESA and NSC (Norway).
