We investigate the consequences of Birkho 's theorem in general relativity (GR) and in Modified Newtonian dynamics (MOND). We study, in particular, the system of a point mass test particle inside a spherical shell. In both GR and MOND, we find non-vanishing acceleration for that test particle. The direction of the acceleration is such that it pushes the test particle toward the center of the shell. In GR, the acceleration is found analytically in the case of a small test mass with a small displacement from the center of the shell. In MOND, the acceleration is found analytically in the limit of large test mass and small displacement, and a comparison to numerical values is made. Numerical simulations are done for more general cases with parameters that mimic the system of a galaxy in a cluster. In GR, the acceleration is highly suppressed, and physically insignificant. In MOND, on the contrary, the acceleration of the point particle can be a significant fraction of the \textit{Einstein} tidal force just outside of the spherical shell.

PACS numbers:

INTRODUCTION

Birkho 's theorem (BT) states that in General Relativity (GR) any spherically symmetric solution of the \textit{Einstein} field equations in vacuum must be stationary and asymptotically flat. As a consequence the metric exterior to a spherically symmetric mass distribution must be a Schwarzschild metric. One important corollary of the theorem is that the metric inside a spherical shell (or inside the innermost sequence of concentric such shells) is the Minkowski metric.

Birkho 's Theorem is the generalization of Newtonian theory to GR of Gauss' Law for gravity. As a consequence of Gauss' Law, outside a spherically symmetric mass distribution, the Newtonian gravitational field is that of a point mass at the center of the distribution. Meanwhile, the gravitational field anywhere inside any spherical mass shell vanishes. In the context of the inverse-square-law of Newtonian gravity, these results are easily understood. For example, at a point inside a spherical shell, the force on a test particle from any thin ring on the shell, is precisely balanced by the force due to a ring subtending the same angle but directly opposite the test ring. Even if the test particle is not at the center. This is because the decrease in the gravitational force due to one ring being farther away from the test particle, is precisely balanced by the increase in area (and so mass) of that farther-away ring.

One can think of Birkho 's theorem as describing the motion of a zero-mass test particle in the presence of a spherically symmetric mass distribution. A zero-mass test particle does not spoil the spherically symmetric. However, in realistic situations, the "test particles" probing a gravitational field have a non-zero mass. Often, this mass is not small at all, as in the case of a large galaxy inside a cluster. Therefore, unless the test particle is at the center of the distribution, its presence perturbs the system from spherical symmetry, spoiling the assumptions underlying BT. This paper addresses the impact this violation of spherical symmetry has both in GR and in theories that implemented ideas of Modified Newtonian Dynamics (MOND).

MOND \cite{Milgrom:1983}, the reader will recall, is an alternative to dark matter in which the missing gravity problem of galaxies is solved by altering the gravitational force law, rather than by introducing new unseen forms of matter.

In both GR and MOND, there are reasons to suspect that the force on a test particle inside a spherical mass shell may not actually vanish. General relativity is a metric theory. Massive bodies change the geometry around them. A mass test particle distorts the space around it and thus a "spherical shell" ceases to be a spherical shell unless the test particle is at its center. This distortion of the test particle will appear in any modification of GR that preserves its metric nature (such as DGP, TeVeS \cite{Khoury:2004}, Generalized Einstein Aether (GEA) and f(R)).

In the case of MOND, which is not itself a metric theory (although its covariant implementations, such as TeVeS and GEA are), the inverse-square law which is crucial for the vanishing acceleration of the test particle inside the shell (or at least for our intuitive understanding of why it vanishes) does not exist. MOND was proposed to explain galactic rotation curves, and therefore is characterized by a gravitational field scaling as $r^{-1}$ instead of $r^{-2}$ at large distances from a bounded mass distribution.

In what follows, we consider the mass distribution shown in Fig. \ref{fig:shells} (a spherical shell of mass $M_1$ plus an interior point mass, $M_2$, of much lower mass.)
**GENERAL RELATIVITY**

In Newtonian mechanics, a spherical shell is a well-defined object. However, in GR, since particles change the geometry around them, the simple definition of a sphere as a set of point equidistant from some common point (the center) is lost in the presence of a perturbing mass. We define a spherical shell usingParametrized Post-Newtonian (PPN) coordinates. We identify a point, such that the distance from the center in PPN coordinates is the same for each point on the shell. We call this distance $R$, the radius of the shell.

We can calculate the acceleration of the test particle in GR from the Einstein-Infeld-Ho classes (EIH) equation [3]:

$$\frac{d^2 x_k}{dt^2} = \frac{dv_k}{dt} = \sum_{\alpha \neq k} \frac{GM}{r_{\alpha k}^3} \left[ \frac{x_{\alpha k} u_{\alpha k}^2}{r_{\alpha k}^2} + \frac{\nu_{\alpha k}^2}{1 - \frac{\nu_{\alpha k}^2}{c^2}} \right]$$

Here $v_k = v_a \times$ and $\xi_b = x_a \times x_b$. $x$ is the spatial variable in the PPN coordinate frame, and $x_k$ is location of object $a$. This equation describes the free-fall of each point in the system. In order to describe the acceleration of the test particle in our system, we should remove from equation [3] the terms that are associated with the acceleration of the shell (which is much smaller than the acceleration of the point particle). The acceleration is then

$$\frac{d^2 x_k}{dt^2} = \frac{dv_k}{dt} = \sum_{\alpha \neq k} \frac{GM}{r_{\alpha k}^3} \left[ \frac{x_{\alpha k} u_{\alpha k}^2}{r_{\alpha k}^2} + \frac{\nu_{\alpha k}^2}{1 - \frac{\nu_{\alpha k}^2}{c^2}} \right]$$

$$= \frac{G^2 M_s M_k}{4\pi^2 R^5} \ln \left( \frac{R - \xi_k}{R + \xi_k} \right) + \frac{2\nu_k R}{(R^2 - \xi_k^2)} \cdot 2$$

In obtaining the final result, we have replaced the sum by an integral over the shell in which we were able to perform. Notice that there is a singularity as $\xi_k \to R$. This singularity is not real. It appears because PPN is not valid as $\xi_k$ is very close to the shell.

Defining $d = \xi = R$, $R_{sch} = 2GM_s$ and $\nu_{sch} = \frac{GM_s}{R}$, equation [2] can be written as

$$\frac{d^2 x_k}{dt^2} = \sum_{\alpha \neq k} \frac{M_k R_{sch}}{M_s} \frac{1}{4d} \left[ \frac{1 - \frac{1}{2d}}{1 + \frac{1}{d}} \right]$$

$$= \sum_{\alpha \neq k} \frac{M_k R_{sch}}{M_s} \left[ \frac{1}{4d} + \frac{2}{(1 - \frac{1}{2d^3})} \right] + \frac{3}{7} \cdot 2$$

where the last line is an expansion for small $d$.

The gravitational acceleration clearly does not vanish if points toward the center. A particle inside a spherical shell is therefore attracted toward the center to restore spherical symmetry, where the acceleration happily does vanish. However, since $M_k = M_s$, the acceleration is very small compared to, say, the Newtonian acceleration just outside the shell, $\nu_{sch}$. It is suppressed by both the ratio of the test mass to the shell mass, and $m$ are in proportion, by the ratio of the Schwarzschild radius $R_{sch}$ of the shell to its physical radius. This suppression factor is huge for typical astrophysical systems, $9.7 \times 10^6$ for our choice of mass and radius. This suppression factor makes the acceleration physically insignificant in GR.
In 1984 Bekenstein and Milgrom introduced the Lagrangian formulation of modified Newtonian dynamics (MOND). The eik equation of MOND is derived from the Lagrangian

\[ L = \int d^3r \left[ \mathcal{E}(r) + \mathcal{V}(r) \right] \]

where \( \mathcal{E}(r) \) is the gravitational potential, \( \mathcal{V}(r) \) is the eik potential, and \( f_0 \) is an arbitrary universal function, that together with \( f_0 \), the characteristic scale of MOND, specifies the theory. Varying \( L \) with respect to \( \mathcal{E}(r) \) yields a modified Poisson equation:

\[ \nabla^2 \mathcal{E} + \frac{\mathcal{E}}{r^2} = 4\pi G \rho \]

where \( \rho \) is the mass density, and \( \nabla^2 \) is the Laplacian operator. The eik scale as \( f_0 \) near a spherical mass distribution (the usual Newtonian result) and as \( f_0 \) far from the mass distribution to explain galaxy rotation curves.

One of the widely used form of \( f_0 \) is

\[ f_0(y) = \frac{y^2}{1 + y^2} \]

(However see \( f_1 \) for different form of function.) The value of \( f_0 \) is then obtained by phenomena, and we will adapt the value derived by Bekenstein et al. in the study of external galaxies with high quality rotation curves.

\[ a_0 = 12 \times 10^{-10} \text{ m/s}^2 \]

Again we consider the mass distribution in Fig. 1. The center of the spherical shell is chosen to be the center of coordinates. Because of the axial symmetry of the concentration, we put the point particle on the z-axis.

We assume that the radius of the shell is large enough that the gravitational acceleration goes deep into the MOND regime. For a bounded mass distribution of total mass \( M \), we define a transition radius

\[ R_t = \frac{P}{GM}a_0 \]

\( R_t \) indicates a point at which the Newtonian eik approximates equals \( a_0 \), and this is the point at which the eik switches from Newtonian \( 1 = r' \) to MOND’s \( 1 = r \). Thus we take \( R = R_t \). For the physical parameters we are considering, \( R = R_t = 4.2 \).

Non-linearity in the modified Poisson equation negates the superposition principle, and it makes an analytic calculation of the eik a non-trivial task. We present the perturbative solution for the case \( M_k < M_s \), and in more general cases, we resort to numerical calculations.

We first consider the mass of the particle inside the shell to be much larger than the mass of the shell. In this case, the density distribution of the spherical shell can be treated as an aspherical perturbation on a spherical system (the point mass and a perturbative solution to them modified Poisson equation is possible. Let the density distribution of the point particle and the spherical shell be \( k \) and \( \text{shell} \), respectively. Then the unperturbed eik \( k \) satisfies the modified Poisson equation:

\[ \mathcal{E}_0 = 4\pi G \rho \]

The exact solution for \( \mathcal{E}_0 \) can be found by applying Gauss’s theorem. In terms of the quantity \( u = \frac{x}{a_0} \),

\[ u^2 = \frac{1}{2}u^2 + \frac{1}{4}u^4 + u^2 \]

The expansion in small \( u \) is valid for \( \frac{x}{a_0} \). Knowing \( \mathcal{E}_0 \), one can find the first-order perturbation equation for \( \mathcal{E}_1 \) using

\[ \mathcal{E}_1 = \mathcal{E}_0 + (1 + u + \ldots) \]

The net force on the shell due to \( \mathcal{E}_1 \) is

\[ F_{\text{shell}} = \frac{M_s}{2\pi R^2} \left[ \frac{1}{R} \frac{1}{R + a_0} \right] \]

The net force on the shell points toward positive \( z \), having the effect of restoring the spherical system by moving the shell so that it is centered on the point mass. The first two terms result from \( \mathcal{E}_1 \) and the last term comes from \( \mathcal{E}_0 \). We note that the first term, which is dominant over other terms, is independent of the specific choice of function. It is a consequence solely of the MOND condition: \( \mathcal{E}(0) \) for \( y \neq 0 \).
The particle in the frame of the shell can be found and expanding in a Taylor series, general activity, it the scale is acceleration in MOND than that in GR. In MOND, the scale of the acceleration is \( a_0 \), but suppressed by \( r_s \approx R \), whereas in general relativity, if the scale is \( g_0 \), but suppressed by \( g_{sch} \approx R \). Since \( R_s \approx R_{sch} \) in general and since \( a_0 \approx g_0 \) for a system deep in the MOND regime, the scale acceleration is much larger in MOND than in GR. For \( M_{total} = 2 \times 10^{14} \) and \( R_{sch} = 2G M_{total} \), the ratio of accelerations is approximately \( a_0 / R \approx g_{sch} = 43 \times 10^6 \).

**Numerical Calculation**

To nd the acceleration of the point particle in a more general case, we adapt the numerical scheme developed by Milgrom [10]. In this scheme, the \( \varepsilon \)U is defined by

\[
\varepsilon U = \nabla \cdot (\varepsilon \nabla U) = \nabla \cdot (\frac{1}{2} \varepsilon + \frac{1}{4} \frac{a_0^2}{U}) \varepsilon U : (15)
\]

So long as \( \varepsilon \) is monotonic, one can invert the relation in equation (15) and write \( r \) in terms of \( U \). For the specific choice of \( \varepsilon \) given by equation (5),

\[
r = \frac{1}{2} + \frac{1}{4} + \frac{a_0^2}{U} : (16)
\]

The \( \varepsilon \)U then satisfies the set of differential equations

\[
r \varepsilon U = 4G : (17)
\]

The discretization and numerical calculation on the lattice is done in terms of \( U \). Because of the one-to-one correspondence between \( r \) and \( U \), one can nd \( r \) from \( U \).

An initial ansatz for \( U_0 \) in the numerical solution is given by solving

\[
r = 4G : (18)
\]

The \( \varepsilon \)U has the correct divergence, but not the correct curl. The code iterates to make the curl vanish at each vertex of the lattice. \( U_0 \) also serves as the boundary condition for the numerical solution. Since \( r \times \varepsilon U \) is zero and \( U_0 \) is zero only by the curl \( \varepsilon \)U. It can be shown [3] that the curl \( \varepsilon \)U for a bounded mass distribution vanishes at least as fast as \( \frac{1}{r} \). Then, assuming that the physical size of the lattice is large compared to the mass distribution, \( U \) \( \varepsilon \)U on the boundary.

We implement Milgrom’s algorithm on a spherical lattice. The point particle is placed at the center of the lattice, and the center of the spherical shell is displaced from the center of the lattice by \( \varepsilon \). The total number of angular grid lines is denoted by \( L \), and the total number of radial grid is \( x \) at \( L = 5 \). To meet the boundary condition, the radius of the outermost shell is set to be \( 100R \).

In the case \( M_k \approx M_s \), a comparison between the numerical results and the perturbative solution is possible. We make the comparison between the solutions with xed values of \( M_s = M_k = 0.51 \) and \( R_k = R = 0.25 \). Fig. 2 shows that these agree to better than one percent. On the plot shown, the percentage di erence varies from 0.1%
FIG. 3: This figure shows the dependence of the numerical solution on the number of lattice sites. The value of $d$ is fixed at $d = 0.02$. The dotted line indicates the value from the perturbation solution.

to 0.9%. The discrepancy between the values increases as $d = n = R$ approaches 1, where the perturbative expansion becomes less reliable. Fig. 3 shows how numerical values depend on the number of lattice points. As expected, the values approach the perturbative solution as $L$ increases. In the following study, we use the lattice size of $L = 300$ and $L = 600$.

Fig. 4 and Fig. 5 represent the results of numerical calculations. The mass dependence of the acceleration of the point particle is plotted in Fig. 4, and the position dependence is plotted in Fig. 5. We see clearly that there is non-vanishing acceleration directed toward the center of the spherical shell. In Fig. 4, we see that the acceleration vanishes in both the $M_k = M_{total}$ and $M_k = 0$. This is expected since these are two limits in which spherical symmetry is recovered. For the three curves plotted in Fig. 4, the peak value occurs around $M_k = M_{total} = 0.15$. The position of the peak has a slight position dependence (as the particle gets closer to the shell, the peak occurs at a smaller $M_k = M_{total}$ ratio).

We note one curious feature from Fig. 4. The astronomically interesting region in Fig. 4 is where $M_k = M_{total} = 0.1$. In this region, the acceleration of the point particle is a very sharp function of its mass. This implies that galaxies with slight mass differences might experience quite different acceleration in theories that implement the MOND limit.

The distance dependence of the acceleration is shown in Fig. 5. Again, the acceleration of the particle vanishes when the particle is near the center ($d = 0$), and increases monotonically outward. Near the shell ($d = 0.2$), the value for $M_k = M_{total} = 0.01$ exceeds that for $M_k = M_{total} = 0.15$. This is because the peak mentioned above occurs at lower value of $M_k = M_{total}$ for larger value of $d$.

Unlike for GR, in MOND the acceleration of the point particle is a significant fraction of $g_0$. Especially when the particle is close to the shell, the acceleration can be larger than $g_0$.

CONCLUDING REMARKS AND IMPLICATIONS

In both general relativity and MOND, the acceleration of a massive test particle inside a spherical mass shell vanishes only when the particle is at the center of the shell. When the particle is displaced from the center, the particle experiences a force toward the center of the shell, the direction in which spherical symmetry would be restored. The magnitude of the acceleration in GR is not physically significant in most (or probably all) astrophysical situations of interest, since it is suppressed by the ratio of the Schwarzschild radius of the shell to the size of the shell.

In MOND, on the contrary, the acceleration of the point particle is a significant fraction of the surface gravity just outside the shell. This is despite the fact that MOND has a Birkhoff or Gauss-like theorem which implies that the potential inside an isolated spherical mass shell is constant. However, this theorem operates in...
Fig. 5: This figure shows the acceleration on the point particle as a function of position for fixed particle-mass to total-mass ratio. Results are plotted for two different mass ratios. The acceleration points toward the center of the shell. Simulations are performed on the lattice with $L = 600$.

The absence of the usual explanation for Gauss’ Law in Newtonian gravity or classical electrostatics (the balance between the $r^2$ growth of surface areas and the $r^2$ force law). Thus, when the very particular conditions of Birkhoff’s theorem are broken even a little, the gravitational force re-emerges at considerable strength. The characteristic MOND field for the values of parameters used in this paper is approximately $\frac{F_{\text{MOND}}}{M_{\text{total}} \cdot a_0} = 0.24 a_0$.

From Fig. 4 and Fig. 5, we can see that the acceleration inside the spherical shell can be significant at this scale.

In MOND, the applicability of Birkhoff’s theorem is very limited, and in computations one needs to consider not only the local mass distribution but also the background mass distribution.
