\textbf{Abstract}

We investigate qualitatively and quantitatively the impact of the general relativistic gravito-electromagnetic forces on hyperbolic orbits around a massive spinning body. The gravito-magnetic field, which is the cause of the well-known Lense-Thirring precessions of elliptic orbits, is generated by the spin \( S \) of the central body. It deflects and displaces the trajectories differently according to the mutual orientation of \( S \) and the orbital angular momentum \( L \) of the test particle. The gravito-electric force, which induces the Einstein precession of the perihelion of the orbit of Mercury, always deflects the trajectories inward irrespective of the \( L \) \( S \) orientation. We numerically compute their effect on the range, radial and transverse components \( v_r \) and \( v_t \) of the velocity and speed \( v \) of the NEAR spacecraft at its closest approach with the Earth in January 1998 when it experienced an anomalous increase of its asymptotic outgoing velocity \( v_\infty \) of 13,460 \( \text{mm sec}^{-1} \); while the gravito-electric force was modeled in the software used to process the NEAR data, this was not done for the gravito-magnetic one. The range and the speed are affected by general relativistic gravito-electromagnetic effect at \( 10^{-2} \) (gravito electric) \( 10^{-5} \) (gravito magnetic) mm sec\(^{-1}\) level. The changes in the range are of the order of \( 10^{-2} \) (gravito magnetic) \( 10^{-1} \) (gravito electric) mm.

1 \textbf{Introduction}

In this paper we will investigate the effects of general relativity, in its weak and slow-motion approximation, on unbound hyperbolic orbits of test particles approaching a body of mass \( M \) and angular momentum \( S \). We will consider both the gravito-magnetic and the gravito-electric relativistic
forces induced by the stationary and static components, respectively, of the
\( e \) of \( M \) [1].

The results obtained will be applied to some realistic planet-spacecraft
scenarios in the Solar System to see if the predicted effects fall within the
current or future sensitivity level of the ranging techniques. In particular, we
will examine the so-called \( \Phi \) anomaly consisting of unexplained changes
of the asymptotic outgoing velocities of some spacecraft (Galileo, NEAR, Cassini and MESSENGER) that occurred at their closest approaches with
the Earth [2, 3].

Let us recall some basics of the Newtonian hyperbolic orbit [4] which
represents, in this case, the reference unperturbed path; see Figure 1. Its

Figure 1: Essential features of the unperturbed Newtonian hyperbola. \( P \) is
the position of a test particle at time with respect to the body located at the
origin of the chosen reference frame. The smallest distance is \( r_{\text{min}} = a(e - 1) \).
The angle between \( r \) and \( v \) is not to be confused with the central
body of mass \( M \).
The equation is
\[ r = \frac{P}{1 + e \cos f}; \]  
(1)

where \( p = a(e^2 - 1) \) is the semilatus rectum, and \( f \) is the true anomaly considered positive in the anti-clockwise direction from the point of closest approach \( A \); \( a \) is the semimajor axis and \( e > 1 \). The speed is
\[ \begin{align*}
\begin{array}{c}
\text{s} \\

v = \frac{GM}{\frac{2}{r} + \frac{1}{a}};
\end{array}
\end{align*} \]  
(2)

so that
\[ \begin{align*}
\begin{array}{c}
\text{r} \\

v_1 = \frac{GM}{a};
\end{array}
\end{align*} \]  
(3)

The asymptotic ingoing and outgoing speeds, which are equal to \( v_1 \) in the unperturbed case, are denoted with \( v_{1\text{i}} \) and \( v_{1\text{o}} \), respectively. The angle between the \( r \) and \( v \) is defined by
\[ \begin{align*}
\begin{array}{c}
\sin \theta = \frac{1 + e \cos f}{1 + e^2 + 2e \cos f};
\end{array}
\end{align*} \]  
(4)

\[ \begin{align*}
\cos \theta = \frac{e \sin f}{1 + e^2 + 2e \cos f};
\end{align*} \]  
(5)

For \( x = 0, y = p \), i.e. \( f = \pi = =2 \), it is
\[ \begin{align*}
\begin{array}{c}
\text{s} \\

v_{x0} = \nabla \sin \psi = \frac{GM}{p};
\end{array}
\end{align*} \]  
(6)

\[ \begin{align*}
\begin{array}{c}
\text{s} \\

v_{y0} = \nabla \cos \psi = e \frac{GM}{p};
\end{array}
\end{align*} \]  
(7)

2 The gravito-magnetic force

In this section we will deal with the effect of the general relativistic gravito-magnetic force on the hyperbolic motion of a test particle approaching a spinning body of mass \( M \) and angular momentum \( S \).

Let us briefly recall that, in the weak-field and slow-motion linear approximation of general relativity, the off-diagonal components \( g_{0i}; i = 1; 2; 3 \) of the space-time metric tensor, related to the mass-energy currents of the source, induce a gravito-magnetic field \( B_g \) [1] by analogy with the magnetic...
eld caused by moving electric charges in the linear Maxwellian electromagnetism. Far from an isolated rotating body, the gravito-magnetic field becomes [5]

$$B_g = \frac{G}{c^3} \left[ S \left( \frac{S}{t} \right) \frac{d}{dt} \right];$$

(8)

where $G$ is the Newtonian gravitational constant and $c$ is the speed of light in vacuum. It exerts the non-central Lorentz-like acceleration [1]

$$A^{GM} = \frac{2}{c} v \cdot B_g$$

(9)

upon a test particle moving with velocity $v$. For ordinary astronomical bodies like, e.g., the Earth and the Sun, $A^{GM}$ is many orders of magnitude smaller than the Newtonian monopole $A^N = GM/r^2$, so that it can be considered as a small perturbation.

The action of eq. (9) in the case of unperturbed close orbits, giving rise to, e.g., the Lense-Thirring precession of the ellipse of a test particle [6, 7, 8], has been the subject of intense activity, both theoretically and observationally, in recent times [9].

Here we will consider as reference path of a Newtonian hyperbolic trajectory. In order to work out the effects of the gravito-magnetic field on it, we will numerically integrate the equations of motion in cartesian rectangular coordinates [10] for some particular orbital geometries over a time span including the epoch of closest approach to $M$ which is assumed located at the origin of the coordinate system.

2.1 Qualitative features for equatorial and polar osculating orbits

First, we will consider a trajectory lying in the equatorial plane of the rotating body for the cases of co-rotation (Figure 2) and counter-rotation (Figure 3) of the particle’s radius vector $r$ with respect to the diurnal rotation of $M$ whose spin $S$ is assumed to be directed along the positive $z$ axis (anticlockwise diurnal rotation). Just for illustrative purposes, we assume the Earth as source of the gravitational field and re-scaled its gravito-magnetic force by a factor $10^{10}$ in such a way to still keeping the condition $A^{GM} = A^N < 1$ valid over the entire orbit. It turns out that the perturbed trajectory remains confined in the equatorial plane of the central body; for co-rotation the path is de-rected outward with respect to the unperturbed hyperbola, while for counter-rotation it is de-rected inward. Indeed, for equatorial orbits $A^{GM}$ is entirely in-plane because $B_g$ is directed along the
Figure 2: Effect of the gravito-magnetic force on the hyperbolic motion of a test particle around an astronomical rotating body located at the origin of the depicted frame. The body's spin $S$ is directed along the positive $z$ axis, i.e., outside the figure. Red line: unperturbed hyperbola. Blue dashed line: perturbed orbit. For illustrative purposes we choose the Earth as central body and re-scaled the magnitude of its gravito-magnetic force by $10^{10}$ so that $A^G = A^N = 0$ at perigee. We adopted the initial conditions $x_0 = 0; y_0 = a(e^2 - 1); z_0 = 0; v_{x0} > 0; v_{y0} > 0; v_{z0} = 0$; the particle moves in the equatorial plane of the spinning Earth in such a way that the radius vector rotates in the same sense with respect to the Earth, i.e., anticlockwise. We used $a = 8493.326$ km, $e = 1.81$. The perturbed orbit is depicted outward with respect to the unperturbed one.
Figure 3: Effect of the gravito-magnetic force on the hyperbolic motion of a test particle around an astronomical rotating body located at the origin of the depicted frame. The body's spin $S$ is directed along the positive $z$ axis, i.e., outside the figure. Red line: unperturbed hyperbola. Blue dashed line: perturbed orbit. For illustrative purposes we choose the Earth as central body and re-scaled the magnitude of its gravito-magnetic force by $10^{10}$ so that $A_{GM} = A_{N} = 0.4$ at perigee. We adopted the initial conditions $x_0 = 0; y_0 = p = a(e^2 - 1); z_0 = 0; v_{x0} > 0; v_{y0} < 0; v_{z0} = 0$; the particle moves in the equatorial plane of the spinning Earth in such a way that the radius vector rotates in the opposite sense with respect to the Earth, i.e., clockwise. We used $a = 8493.126$ km, $e = 1.81$. The perturbed orbit is deccelerated inward with respect to the unperturbed one.
negative z axis; for co-rotating particles it is radially directed outward at the point of closest approach and decreases the gravitational pull felt by the orbiter, while for counter-rotating probes it is radially directed inward at the pericentre and increases the net gravitational acceleration. The yby epoch is left almost unaffected. By taking the difference between the integrated perturbed and unperturbed orbits sharing the same initial conditions, it can be shown that in the co-rotating case the radial velocity, which is one of the direct observables in real planet-spacecraft close encounters, experiences an increase with respect to the unperturbed one just around the yby epoch, while the radial components of \( v_{1} \) and \( v_{1} \) are left unaffected. In the counter-rotating case \( v_{1} \) decreases at the closest approach. Concerning the body-centric range \( r \), it turns out that it suddenly increases (decreases) around the yby epoch for the co-(counter-)rotating case and remains about at that level also after the yby.

Let us, now, consider the case in which the unperturbed hyperbola entirely lies in an azimuthal plane, e.g. the fyzg plane, containing the spin \( S \) of the central body. Now, since \( v \) is contained in the same plane of \( B_{g} \), the gravitational magnetic acceleration is out-of-plane, so that it can be expected that the perturbed trajectory will be displaced along the \( x \) axis. This fact is confirmed by a numerical integration shown in Figure 4 and Figure 5 from which the displacement of the orbit perpendicularly to the initial osculating plane is apparent.

2.2 The yby anomaly: the NEAR case

Many spacecraft launched in interplanetary missions make use of one or more Earth's ybys in order to gain or lose the heliocentric energy required to reach their far targets (planets, asteroids, comets) without using huge and expensive amounts of propellant [11, 12]. In the case of GALILEO (twice), NEAR, Cassini and MESSENGER unexplained variations in \( v_{1} \) were detected [2, 3]; the largest one was measured at the close encounter of NEAR with the Earth that occurred in 1998 and amounted to

\[
v_{1} = 13 \times 0.01 \text{ m m sec}^{-1}.
\]

The unperturbed hyperbola of NEAR is depicted in Figure 6.

Anderson et al. in [3] derived an empirical formula which satisfactorily describes all the six yby anomalies measured so far. It is

\[
\frac{v_{1}}{v_{1}} = \frac{2!R}{c} \cos \phi = 3.999 \times 10^{-6} \cos \phi \times \cos \phi;
\]

\[
(10)
\]

\[
(11)
\]
Figure 4: Effect of the gravito-magnetic force on the hyperbolic motion of a test particle around an astronomical rotating body located at the origin of the depicted frame. The body's spin $S$ is directed along the positive $z$ axis, i.e. outside the figure. For illustrative purposes we choose the Earth as central body and re-scaled the magnitude of its gravito-magnetic force by $10^{10}$ so that $A^{GM} = A^N = 0.4$ at perigee. We adopted the initial conditions $x_0 = 0; y_0 = p = a(e^2 - 1); z_0 = 0; v_{x0} = 0; v_{y0} > 0; v_{z0} > 0$ to have the spacecraft initially moving in the osculating $fyzg$ plane. The perturbed trajectory is displaced along the $x$ axis on the upper left corner.
Figure 5: Effect of the gravito-magnetic force on the hyperbolic motion of a test particle around an astronomical rotating body located at the origin of the frame shown with its spin directed along the positive z axis, i.e. outside the figure. For illustrative purposes we choose the Earth as central body and re-scaled the magnitude of its gravito-magnetic force by $10^{10}$ so that $A_{GM}^{N} = A_{N}^{N} = 0$ at perigee. We adopted the initial conditions $x_0 = 0; y_0 = p = a(e^2 - 1); z_0 = 0; v_{x0} = 0; v_{y0} < 0; v_{z0} > 0$ to have the spacecraft initially moving in the osculating $fyz$ plane. The perturbed trajectory is displaced along the $x$ axis on the lower right corner.
Figure 6: Unperturbed hyperbola of NEAR; its osculating plane is tilted by 108 deg to the \( fx;yg \) plane assumed coincident with the Earth's equator. The starting point is in the right upper corner \((x_0 > 0; y_0 > 0; z_0 > 0)\). The Earth has to be imagined located at the origin of the coordinate system with its spin \( S \) directed along the positive \( z \) axis.
where $v$ and $R$ are the Earth’s angular speed and equatorial radius, respectively, while $i$ and $o$ are the ingoing and outgoing geocentric declinations, respectively. Concerning possible explanations in terms of known physics, many dynamical effects (tides, atmospheric drag, Earth’s albedo, solar wind, terrestrial magnetic field, spin-rotation coupling between electromagnetic waves and spacecraft and Earth rotations) were preliminarily considered by Lam et al. in [13]; an order-of-magnitude approach was followed by confronting the magnitude of the accelerations induced by standard forces with that which is assumed to be responsible of the yby anomaly, i.e., $10^4 \text{ m sec}^{-2}$. As a consequence, all the effects investigated were discarded. However, we note that detailed analyses are in order: indeed, even if some dynamical effect, standard or not, was found to produce an acceleration with the right order of magnitude, it might happen that its signature on the observable quantities is not correct; that is, it may induce, for instance, a decrease of the radial velocity. M. Bekle in [14] suggested that the special relativistic Doppler effect may explain the formula by Anderson et al. [3]. Among various explanations in terms of non-conventional physics put forth so far, McCullough in [15] proposed a mechanism based on the hypothesis that inertia is due to a form of Unruh radiation and varies with acceleration due to a Hubble-scale Casimir effect. It qualitatively reproduces the latitude-dependence of eq. (11) and is quantitatively in agreement with three of the six measured ybys.

Since eq. (11) contains a term including quantities like the speed of light and the first power of the Earth’s angular speed which enters general relativistic gravito-magnetic effects, it seems interesting to apply our previous results concerning the influence of $B_0$ on hyperbolic orbits to the NEAR’s yby. Note that the gravito-magnetic force was not modeled in the software used to process the NEAR data. By using the state vector of NEAR at the yby epoch (J. Anderson, private communication to the author, November 2008) referred to a geocentric equatorial frame $f_{\text{xy}}$, and eq. (9) it turns out that at the point of closest approach to Earth along the yby trajectory

$$A_{x}^{GM} = 3.3 \times 10^{10} \text{ m sec}^{-2};$$

$$A_{y}^{GM} = 7.5 \times 10^{11} \text{ m sec}^{-2};$$

$$A_{z}^{GM} = 1.7 \times 10^{10} \text{ m sec}^{-2};$$

so that

$$A^{GM} = 3.8 \times 10^{10} \text{ m sec}^{-2};$$

We will now use a numerical integration of the equations of motion perturbed by eq. (9). We look at a time span starting from the yby epoch
Figure 7: Change in the radial velocity \( v_r \) induced by the gravito-magnetic force on NEAR at the Earth’s yby (1998-Jan-23 07:22:56 Coordinate Time (CT)). It has been obtained by taking the difference between the integrated perturbed and unperturbed trajectories sharing the same initial conditions of Table 1. They have been obtained with the HORIZONS software by NASA JPL at 1998-Jan-23 07:00:00 CT and correspond to an instant 1353 sec before the yby. Reference frame: ICRF/J2000.0. Coordinate system: Earth Mean Equator and Equinox of Reference Epoch. The maximum effect \( v^\max_r = 5 \times 10^{-5} \text{ m sec}^{-1} \) occurred just at the yby.

and extending in the future after it: the chosen initial conditions are in Table 1. We will consider the changes of the velocity along the radial \( \hat{r} \), transverse \( \hat{\tau} \) and out-of-plane \( \hat{z} \) directions; \( \hat{r} \) is directed along the orbital angular momentum, while \( \hat{\tau} = \hat{\tau} \) is not directed, in general, along \( \hat{r} \).

The results for \( v_r \), \( \dot{v} \), \( v \) and \( r \) are shown in Figure 7-Figure 10, respectively. They have been obtained by subtracting the unperturbed orbit from the perturbed one, both numerically integrated with the initial conditions of Table 1.

The gravito-magnetic force of the Earth decreased the radial velocity of NEAR by \( 10^{-5} \text{ m sec}^{-1} \) just at the yby, while the transverse velocity was augmented after the yby up to \( 10^{-5} \text{ m sec}^{-1} \) level; it turns out that the normal velocity was affected at an even smaller level. The total speed

Figure 8: Change in the transverse velocity $v$ induced by the gravito-magnetic force on NEAR at the Earth's yby (1998-Jan-23 07:22:56 CT). The maximum value reached is of the order of $10^{-5}$ m m sec$^{-1}$. 
Figure 9: Change in the speed $v$ induced by the gravito-magnetic force on NEAR at the Earth's yby (1998-Jan-23 07:22:56 CT). The maximum effect $v_{\text{max}} = 2 \times 10^5 \text{ mm sec}^{-1}$ occurred just at the yby while $v_{\text{1 o}}$ is left almost unchanged.
Figure 10: Change in the radial distance $r$ induced by the gravito-magnetic force on NEAR at the Earth's yby (1998-Jan-23 07:22:56 CT). The maximum effect $r_{\text{max}} = 6 \times 10^{-2}$ mm took place after the yby.
v was increased up to $10^5$ m m sec$^{-1}$, i.e., six orders of magnitude smaller than the observed increment. The geocentric range of the spacecraft was reduced by about $10^2$ m m.

3 The gravito-electric force

In the Post-Newtonian approximation of order $O(c^{-2})$, the acceleration induced by the gravito-electric component of the field of a static mass $M$ is, in standard isotropic coordinates, [10]

$$A^{GE} = \frac{GM}{c^2} \frac{4GM}{r^4} r \frac{v^2}{r^3} r + \frac{4(r - v)}{r^3} v :$$  \hspace{1cm} (16)

Concerning the influence of eq. (16) on the hyperbolic motion, it has only radial and transverse components, so that no departures from the osculating plane occur. From Figure 11 it turns out that the test particle is deflected inward with respect to the unperturbed hyperbola.

The gravito-electric acceleration experienced by NEAR at the point of closest approach to earth along the yby trajectory was

$$A^{GE}_x = 9.5 \times 10^{-10} \text{ m sec}^{-2};$$  \hspace{1cm} (17)

$$A^{GE}_y = 5.26 \times 10^{-9} \text{ m sec}^{-2};$$  \hspace{1cm} (18)

$$A^{GE}_z = 3.42 \times 10^{-9} \text{ m sec}^{-2};$$  \hspace{1cm} (19)

so that

$$A^{GE} = 6.35 \times 10^{-9} \text{ m sec}^{-2};$$  \hspace{1cm} (20)

The impact of the gravito-electric force on $v_x$, $v_y$, $v$, and $r$ of NEAR at its yby are depicted in Figure 12-Figure 15, respectively; their patterns are quite different from the gravito-magnetic ones; the outgoing asymptotic velocity is changed by an amount of the order of $10^{-3}$ m m sec$^{-1}$. The maximum variations of the range rate, the transverse velocity, the speed, and the range are of the order of $10^{-2}$ m m and $10^1$ m m, respectively.

\hspace{1cm} 1\text{Contrary to the gravito-magnetic one, it was modeled in the software used for processing the data.}
Figure 11: Effect of the gravito-electric force on the hyperbolic motion of a test particle around an astronomical body located at the origin of the frame shown. Red line: unperturbed hyperbola. Blue dashed line: perturbed orbit. For illustrative purposes we choose the Earth as central body and re-scaled the magnitude of its gravito-electric force by $10^8$ so that $A_{GE}^N = 0.1$ at perigee. We adopted the initial conditions $x_0 = 0; y_0 = 0; \ p = a(e^2 - 1); \ z_0 = 0; \ v_{x0} > 0; \ v_{y0} > 0; \ v_{z0} = 0$. We used $a = 8493326 \text{ km}, e = 1.81$. The perturbed orbit is deected inward with respect to the unperturbed one.

4 Discussions and conclusions

We investigated qualitatively and quantitatively the impact of general relativity, in its weak-field and slow-motion approximation, on unbound hyperbolic orbits around a massive spinning body. We considered both the gravitomagnetic and the gravitoelectric terms; the first one is responsible of the Lense-Thirring precessions of elliptic orbits, while the second one causes the well known Einstein precession of the perihelion of Mercury of 43.98 arcsec/cy. The gravitomagnetic force dectects an equatorial trajectory inward or outward with respect to the unperturbed hyperbola according to the mutual orientation of the orbital angular momentum $L$ of the particle with respect to the spin $S$ of the central body. For osculating orbits lying in a plane which contains $S$ there is also a displacement in the out-of-plane direction. The gravitoelectric force is not sensitive to the $L$ $S$ orientation and detects the trajectory inward with respect to the unperturbed hyperbola.

We applied our results to the yby anomaly experienced by the NEAR spacecraft at its close encounter with the Earth on January 1998 when its asymptotic outgoing velocity $v_1$ was found larger than the ingoing one by
13:46 0.01 mm sec$^{-1}$; contrary to the gravito-electric force, the gravito-magnetic one was not modeled in the software used to process the NEAR data. From numerical integrations of the perturbed equations of motion in a geocentric equatorial frame with rectangular cartesian coordinates over a time span extending in the future after the flyby epoch, we quantitatively investigated the changes in the radial and transverse components of the velocity $v_r$ and $v_t$, the speed $v$ and the range $r$ of NEAR induced by the general relativistic gravito-electromagnetic forces. Concerning the range, its variations are at the $10^{-2}$ level for the gravito-magnetic force and $10^{-1}$ mm level for the gravito-electric one. The radial and transverse velocities and the speed are acted at $10^{-2}$ (gravito-electric) and $10^{-5}$ (gravito-magnetic) mm sec$^{-1}$ level.
