We calculate neutrino processes involving two nucleons at subnuclear densities using chiral effective field theory. Shorter-range noncentral forces reduce the neutrino rates significantly compared with the one-pion exchange approximation currently used in supernova simulations. For densities \( \langle N \rangle \lesssim 10^{14}\text{g cm}^{-3} \), we nd that neutrino rates are well constrained by nuclear interactions and nucleon-nucleon scattering data. As an application, we calculate the mean-square energy transfer in scattering of a neutrino from nucleons and find that collision processes and spin-dependent mean-eld ects dominate over the energy transfer due to nucleon recoil.

Neutrino processes involving two nucleons (NN) play a special role in the physics of core-collapse supernovae and neutron stars: Neutrino-pair bremsstrahlung and absorption, \( \text{NN} \leftrightarrow \text{NN} \), are key for the production of muon and tau neutrinos, for their spectra, and for equilibrating neutrino number densities \( \langle N \rangle \). Since neutrinos interact weakly, the rates for neutrino emission, absorption and scattering are determined by the dynamical response functions of strongly-interacting matter. Supernova explosions are most sensitive to neutrino processes near the protoneutron star, at subnuclear densities \( \langle N \rangle = 10^{14}\text{g cm}^{-3} \), being the saturation density), and where matter is neutron rich. In this regime, there exist to date no systematic calculations of neutrino rates that go beyond the one-pion exchange (OPE) approximation for the nucleon-nucleon interaction. In this paper, we present rst results for neutrino processes in neutron matter based on chiral effective eld theory (EFT).

Noncentral contributions to strong interactions, due to tensor forces from pion exchanges and spin-orbit forces, are essential for the two-nucleon response. This follows from direct calculations of neutrino-pair bremsstrahlung \( \text{NN} \leftrightarrow \text{NN} \) and from conservation laws \( \Delta S = 0 \). In supernova and neutron star simulations, the standard rates for bremsstrahlung and absorption are based on the OPE approximation \( \Delta S = 0 \). This is a reasonable starting point, since it represents the long-range part of nuclear forces, and for neutron matter, it is the leading-order contribution in chiral EFT \( \Delta S = 0 \). However, for the relevant Fermi momentum \( k_F \), 10 fm \(^{-1}\) \( \approx 200\text{MeV} \), subleading noncentral contributions are crucial for reproducing NN scattering data \( \Delta S = 0 \). In this paper, we go beyond the OPE approximation and include contributions up to next-to-next-to-leading order (N\(^3\)LO) in chiral EFT. We nd that shorter-range noncentral forces signicantly reduce the neutrino rates for all relevant densities. As an application, we calculate the mean-square energy transfer in scattering of a neutrino from nucleons and nd that collision processes and spin-dependent mean-eld ects are more important than nonzero mean-eld transfers to the nucleons. This establishes that the long-wavelength approximation used in the OPE calculations \( \Delta S = 0 \) is reasonable.

We follow the approach to neutrino processes in nucleon matter developed in Ref. \( \Delta S = 0 \), which is based on Landau’s theory of Fermi liquids and consistently includes one-quasiparticle-quasihole pair states (corresponding to elastic scattering of neutrinos from nucleons) and two-quasiparticle-quasihole pair states, which are taken into account through the collision integral in the Landau transport equation for quasiparticles. Using a relaxation time approximation, the transport equation can be solved and this leads to a general form for the response functions \( \Delta S = 0 \). The spin response includes multiple-scattering effects, thereby taking into account the Landau-Pom eranchuk-Migdal (LPM) effect, and generalizes earlier work to : dilation wave lengths.

\[ C(k_F) = \begin{cases} \text{LO (one-pion exchange)} & \text{for } k_F \lesssim 10^{-1} \text{fm}^{-1} \\ \text{NLO} & \text{for } 10^{-1} \text{fm}^{-1} \lesssim k_F \lesssim 10^{-2} \text{fm}^{-1} \\ \text{N}^3\text{LO} & \text{for } k_F \gtrsim 10^{-2} \text{fm}^{-1} \end{cases} \]

**FIG. 1:** (Color online) Spin relaxation rate given by \( C \) of Eq. \( \Delta S = 0 \) as a function of Fermi momentum \( k_F \), obtained from chiral EFT interactions of successively higher orders \( \Delta S = 0 \). All results are for \( m = m = 1 \).
Basic formism. In supernovae and neutron stars, the energy and momenta of the system are small compared to the Fermi energy, $T = \hbar \nu$. This is the regime in which Landau's theory of Fermi liquids is a reasonable first approximation, and includes the conditions under which the two-nucleon response is effective. We focus on axial current processes, since they dominate in many situations and are most affected by NN interactions. The corresponding neutrino rates are given by [11]

$$
\langle |\gamma| q \rangle = 2 \, n G_F^2 C_A^2 \left( \cos \theta \right) S_A (|\gamma| q); \quad (1)
$$
multiplied by occupation probabilities for the initial neutrino states and Pauli-blocking factors for final states. Here $n$ denotes the neutron number density $G_F$ the Fermi coupling constant, $C_A = g_s = 2 = 1.26$, and the axial-vector coupling for neutrinos, and is the angle between the initial and final neutrino momenta for scattering, or between the neutrino and the antineutrino momenta and minus the antineutrino. In addition, we consider degenerate conditions, where the temperature is small compared to the Fermi energy, $T = \hbar \nu$. This is the regime in which Landau's theory of Fermi liquids is a reasonable first approximation, and includes the conditions under which the two-nucleon response is effective. We focus on axial current processes, since they dominate in many situations and are most affected by NN interactions. The corresponding neutrino rates are given by [11]

$$
\langle |\gamma| q \rangle = 2 \, n G_F^2 C_A^2 \left( \cos \theta \right) S_A (|\gamma| q); \quad (1)
$$
multiplied by occupation probabilities for the initial neutrino states and Pauli-blocking factors for final states. Here $n$ denotes the neutron number density $G_F$ the Fermi coupling constant, $C_A = g_s = 2 = 1.26$, and the axial-vector coupling for neutrinos, and is the angle between the initial and final neutrino momenta for scattering, or between the neutrino and the antineutrino momenta and minus the antineutrino.

$$
\frac{1}{T} = C \left( 1 - |\gamma| q \right) \quad \text{with} \quad C = \frac{3m}{6k_F^2} \left( \frac{1}{12} \right)_{k=1, \rho, \beta}
$$

where $A_{1; j^0}(k; k^0)$ is the quasi-particle scattering amplitude multiplied by $N(0)$, $k = p_1 + p_2$ and $k^0 = p_1 + p_2$ are the nucleon momenta, and the average $\frac{1}{12}$ is over the Fermi surface (for details see [13]). The commutator with the two-body spin operator demonstrates that only non-central interactions contribute.

$$
\frac{1}{T} = C \left( 1 - |\gamma| q \right) \quad \text{with} \quad C = \frac{3m}{6k_F^2} \left( \frac{1}{12} \right)_{k=1, \rho, \beta}
$$

where $A_{1; j^0}(k; k^0)$ is the quasi-particle scattering amplitude multiplied by $N(0)$, $k = p_1 + p_2$ and $k^0 = p_1 + p_2$ are the nucleon momenta, and the average $\frac{1}{12}$ is over the Fermi surface (for details see [13]). The commutator with the two-body spin operator demonstrates that only non-central interactions contribute.

$$
C = \frac{16}{9k_F} \sum_{m, m'} \left( \frac{1}{12} \right)_{j=1, \rho, \beta}
$$

where $j, \beta$ are total angular momentum, $m$ is the magnitude of the relative momenta, and $p$ is the magnitude of the relative momenta. We use $b = 2 \alpha + 1$ and standard notation for Clebsch-Gordan, $j$ and $6j$ symbols [13].

Results. In Fig. [1], we show the spin relaxation rate calculated from chiral EFT interactions up to $N^3 O^6$ as a function of the Fermi momenta over a wide density range ($k_F = 1.4 \, \text{fm}^{-1}$ corresponds to $\rho = m k_F^2 = 1.5 \times 10^{11} \, \text{g/cm}^3$) [23]. The neutrino-pair bremsstrahlung and absorption rates are proportional to $C$ to a good approximation when $j \geq 1$, while for larger val-

$$
\frac{1}{T} = C \left( 1 - |\gamma| q \right) \quad \text{with} \quad C = \frac{3m}{6k_F^2} \left( \frac{1}{12} \right)_{k=1, \rho, \beta}
$$

where $A_{1; j^0}(k; k^0)$ is the quasi-particle scattering amplitude multiplied by $N(0)$, $k = p_1 + p_2$ and $k^0 = p_1 + p_2$ are the nucleon momenta, and the average $\frac{1}{12}$ is over the Fermi surface (for details see [13]). The commutator with the two-body spin operator demonstrates that only non-central interactions contribute.
ues of $C$ they are suppressed by the LPM effect \cite{11,12}. The leading order (LO) contribution includes OPE as the only noncentral interaction, which provides the standard two-nucleon rates used in current supernova simulations. Our results based on chiral EFT interactions of successively higher orders of $\xi$PA \cite{13} show that OPE signal overestimated $C$ for all relevant densities. The bands at next-to-leading order (NLO), $N^2\text{LO}$, and $N^3\text{LO}$ provide an estimate of the theoretical uncertainty, generated by varying the cut-off as well as a spectral function cut-off in the irreducible 2-exchange $\text{SF} \ (8,14)$. Chiral EFT interactions at $N^2\text{LO}$ accurately reproduce low-energy $N\bar{N}$ scattering \cite{12,13}, and at this order, $C$ is practically independent of the $N^\text{LO}$ potential for these densities. Most of the reduction of $C$ occurs at the NLO level, which includes the leading 2-exchange tensor force (for $\text{SF} \neq 1$)

$$V_{N\text{LO}}^{2\text{ex}} = \frac{3}{64} k_2 \left( \frac{\sqrt{\frac{w}{2m}}}{k} \right)^2 \frac{w + k}{2m};$$

and shorter-range noncentral contact interactions

$$V_{\text{NC}}^{N^3\text{LO}} = \xi_1 k_2 \eta_2 \xi \eta + \xi_1 (1-2) (k \eta);$$

where $w = \frac{p^2}{2m^2} + k^2$ and $\xi_i$ are constrained by NN scattering data (S- and $P$-waves). $V_{N\text{LO}}^{2\text{ex}}$ added to OPE increases $C$ (to 0.29 MeV \cite{12} at $k_F = 1.0\text{fm}^{-1}$), but this is compensated by the repulsive short-range noncentral $V_{\text{NC}}^{N^3\text{LO}}$.

Energy transfer. Figure 2 shows the impact of $C$ on the root-mean-square (rms) energy transfer $E$ in scattering from nucleons. In the absence of Pauli blocking of final neutrino states, $E$ is given by

$$E^2 = \frac{R}{\text{d}P} \left( \begin{array}{c} E \ E^2 \ \overline{E^2} \ \overline{P} \ \overline{P} \end{array} \right);$$

For the $N^3\text{LO}$ results, the comparison with the long-wavelength approximation ($q = 0$) shows that the energy transfer due to nucleon recoil is small. Collision processes are the major contributor to the energy transfer. This is clear from the decreased $E$ with the lower $C$ value. In addition, the comparison with the $G_0 = 0$ results demonstrates the increased energy transfer due to repulsive mean- and eddies in the spin channel.

Comparison of interactions. We have also carried out calculations for the Entem and Machleidt (EM) $N^3\text{LO}$ potentials \cite{15} and chiral $\text{NLO}$ interactions \cite{13} and the result based on phase shifts. We also include the results of Ref. \cite{15} for $V_{\text{low}}$ with a density-dependent cut-off $= 2\text{fm}^{-1}$. All results are for $m = 1$ (i.e., $1.0\text{MeV} = 2\text{fm}^{-1}$) over the range $k_F$.

Compared with interactions, we have also carried out calculations for the EM and Machleidt (EM) $N^3\text{LO}$ potentials with $= 500$ and $600\text{MeV} \ (15)$. The EM $500\text{MeV}$ results overlap with the EM $N^3\text{LO}$ band of Fig. 1. The EM $600\text{MeV}$ rate is larger due to the failure of the Born approximation in this case. We have also used the renormalization group (RG) \cite{16} to evolve all $N^3\text{LO}$ potentials to low-m on entum interactions $V_{\text{low}} = 1.0\text{MeV} = 2\text{fm}^{-1}$ (300-500 MeV) to extend the estimate of the theoretical uncertainty. The RG preserves the long-range pion exchanges and includes sub-leading contact interactions, so that NN scattering data are reproduced. The resulting $C$ band is shown in the
upper panel of Fig. [3]. This includes the rate based on the evolved EM 600 MeV potential.

In the low-density limit, two-nucleon collisions dominate and NN phase shifts provide a model-independent result for the spin relaxation rate. In the near-degenerate case, the strong potential \( V \) in Eq. [5] is then replaced by the free-space \( K \) matrix, since Pauli blocking remains over the imaginary parts from the loop integrals in the \( T \)-matrix equation. We use the standard expression of the \( K \) matrix in terms of an optical phase shift and mixing angles from the \( N \) eigen Partial Wave analysis (nn-online.org). In general, it is never clear whether an expansion in terms of the free-space \( K \) matrix (or the \( T \) matrix) is reliable for \( k_F \) > 1 f. m. due to large scattering lengths and Pauli blocking for near-degenerate conditions, unless the relevant parts of \( V \) are perturbative. Neutrino-pair bremsstrahlung neglecting mean-fields and LPM effects has been calculated from the \( T \) matrix in Ref. [19]. For all densities in Fig. [3] we find the striking result that the chiral EFT and \( V_{\text{LO}} \) rates obtained in Born approximation are close to those from phase shifts (with the \( K \) matrix). This denonstrates that, for these lower cutoffs, the noncentral part of the neutron-neutron amplitude is perturbative in the particle-particle channel.

The upper panel of Fig. [3] combines our results based on nuclear interactions and NN phase shifts, and also includes rates from \( V_{\text{LO}} \) interactions [10] that extend to higher densities. At subnuclear densities < \( 10^{14} \) g cm\(^{-3} \) (\( k_F < 1.2 \) f. m.\(^{-1} \)), the spin response is well constrained and all results lie within a band, with a significantly reduced \( C \) compared to OPE. For \( k_F > 1.5 \) f. m.\(^{-1} \), calculations of the equation of state show that low-momentum NN interactions become important [20] and should be included. In the lower panel of Fig. [3] we show a simple representation of our results,

\[
C_{\text{LO}}(g F) = \frac{0.56}{1 + 0.9(k_Ff m^{-1})^3}\; \mbox{MeV}^{-1}
\]

that, together with the spin response function given by Eqs. [4] and [5], can be used in astrophysical simulations.

Any-body \( e \) effects. Our results above do not include the \( e \) effects of the nuclear medium on collisions. To give a sense of how these \( e \) effects, we show the lower panel of Fig. [3] rates that include second-order many-body contributions (particle-particle/hole-hole and particle-hole) and self-energy effects through the effective mass (according to Eq. [6], \( C = m^{-1} \)) [16]. Both particle-hole and many-body \( e \) effects reduce the spin relaxation rate. The former is driven by second-order particle-hole mixing tensor with strong central interactions [21]. This denonstrates the need to study in greater detail the influence of many-body \( e \) effects on collisions (see also Ref. [22]).

In summary, we have presented the first calculations of neutrino processes in supernovae based on chiral EFT. Our N\(^3\)LO results over the inportant density range \( 10^{14} \) g cm\(^{-3} \) represent a significant advance beyond the OPE rates currently used in simulations. Shorter-range noncentral forces reduce the rates significantly. For densities < \( 10^{14} \) g cm\(^{-3} \), the spin response is well constrained by nuclear interactions and NN scattering data. Future work will include neutron-proton mixtures and charged currents, to systemically improve the neutrino physics input for astrophysics.

We thank S. Bogner, M. Liebendorfer, and A. Nogga for useful discussions, and the Niels Bohr International Academy and NORDITA for their hospitality. This work was supported in part by NSERC and the NRC Canada.

[23] For all results, we found excellent convergence with partial waves \( jj_6 \). In addition, we checked that the spin relaxation rate for OPE expanded in partial waves reproduces the analytical result (Eq. (38) in Ref. [10]).
