New Strong-Field QED Effects at ELI: Nonperturbative Vacuum Pair Production

Gerald V. Dunne

Department of Physics, University of Connecticut, Storrs CT 06269-3046, USA

Since the work of Sauter, and Heisenberg, Euler and Kockel, it has been understood that vacuum polarization effects in quantum electrodynamics (QED) predict remarkable new phenomena such as light-light scattering and pair production from vacuum. However, these fundamental effects are difficult to probe experimentally because they are very weak, and they are difficult to analyze theoretically because they are highly nonlinear and/or nonperturbative. The Extreme Light Infrastructure (ELI) project opens the possibility of a new window into this largely unexplored world. I review these ideas, along with some new results, explaining why quantum field theorists are so interested in this rapidly developing field of laser science. I concentrate on the theoretical tools that have been developed to analyze nonperturbative vacuum pair production.

I. INTRODUCTION

The Extreme Light Infrastructure (ELI) project will provide lasers with electromagnetic fields of unprecedented intensity, allowing a new experimental window into the largely unexplored regime of nonperturbative quantum electrodynamics (QED). This has implications not just for QED, but also for fundamental issues in quantum field theory, as well as nuclear, atomic, plasma, gravitational and astrophysical physics. Quantum vacuum fluctuations mean that the QED vacuum behaves like a polarizable medium that modulates classical behavior, leading to novel quantum effects [2-6,8,9]. Many of these, such as the Lamb shift [7], DeBroglie scattering [9], photon splitting [10,11], nonlinear Compton scattering [12], and the Casimir effect [13,14,15], have been experimentally observed, while others such as elastic photon-photon scattering and nonperturbative electron-positron pair production from vacuum, have not yet been observed. This is essentially because they are very weak effects. Our current understanding of the perturbative regime of QED is extremely good. The classic example is the anomalous magnetic moment of the electron [defined by the proportionality between magnetic moment and spin: $\gamma = g - 2\mu_0 S$], concerning which there has been dramatic recent progress, both experimentally and theoretically. On the theoretical side [16], a four-loop computation [involving 891 four-loop Feynman diagrams!], gives $g$ as a series in the fine structure constant $\alpha$: $g = \alpha - 2\alpha^2 + 3\alpha^3 + 4\alpha^4 + \cdots$ (1.1)

On the experimental side [17], a single-electron cyclotron has been used to measure $g$ directly, without measuring $\alpha$, and the result agrees remarkably well with the value obtained from (1.1) using a precise independent measurement of the atomic $\alpha$.

On (from atom $\alpha$): $g = \frac{2}{\alpha} = 0.001159 652180 73$ (28)

On Rb: $g = \frac{2}{\alpha} = 0.001159 652178 86$ (1.2)

This is an impressive confirmation of the precision of perturbative QED.

By contrast, we know very little about the nonperturbative regime of QED that arises when we consider QED in ultra-strong external fields. To quantify "ultra-strong", recall the computation of Heisenberg and Euler [2] of the probability of vacuum pair production in an applied uniform electric field of strength $E$. Vacuum pair production is a process in which virtual dipole pairs in the vacuum can be accelerated apart by the external field, becoming real asymptotic electron pairs if they gain the binding energy of $2m^2c^3$ from the external field, as depicted in Figure 1. This is a non-perturbative process, and the leading exponential part of the probability, assuming a constant electric field, was computed by Heisenberg and Euler [2,3]:

$$\text{P}_{\text{HE}} = \exp\left(-\frac{m^2 c^3}{e E h}\right);$$ (1.3)
FIG. 1: Pair production as the separation of a virtual vacuum dipole pair under the influence of an external electric field.

Building on earlier work of Sauter [10]. This result sets a basic scale of a critical electric strength and intensity near which we expect to observe such nonperturbative effects:

\[ E_c = \frac{m^2 c^3}{\epsilon h} \quad 10^6 \text{ V = cm} \]
\[ I_c = \frac{c}{8} E_c^2 \quad 4 \times 10^9 \text{ W = cm}^2 \]  
(1.4)

As a useful guiding analogy, recall Oppenheimer’s computation [13] of the probability of ionization of an atom by a uniform electric field:

\[ P_{\text{ionization}} = \frac{4}{3} \left( \frac{p}{2m} \right)^{3-2} \exp \left( \frac{2m^2 e^4}{3 \epsilon h} E_b \right) \]  
(1.5)

Taking as a representative atom scale the binding energy of hydrogen, \( E_b = \frac{m^2 e^4}{2m} \approx 13.6 \text{ eV} \), we find

\[ P_{\text{hydrogen}} = \exp \left( \frac{2m^2 e^4}{3 \epsilon h} E_b \right) \]  
(1.6)

This result sets a basic scale of electric strength and intensity near which we expect to observe such nonperturbative ionization effects in atomic systems:

\[ E_{c,\text{ionization}} = \frac{m^2 e^4}{\hbar^2} = \frac{3}{4} E_c \quad 4 \times 10^6 \text{ V = cm} \]
\[ I_{c,\text{ionization}} = \frac{6}{3} I_c \quad 10^9 \text{ W = cm}^2 \]  
(1.7)

These, indeed, are the familiar scales of ionization experiments. Note that \( E_{c,\text{ionization}} \) differs from \( E_c \) by a factor of \( \frac{3}{4} \times 10^7 \). These simple estimates explain why vacuum pair production has not yet been observed (it is an astonishingly weak effect with conventional lasers [22,23]). This is because it is primarily a non-perturbative effect, that depends exponentially on the (inverse) electric field strength, and there is a factor of \( 10^7 \) difference between the critical electric scales in the atom regime and in the vacuum pair production regime. Thus, with standard lasers that can routinely probe ionization, there is no hope to see vacuum pair production. However, recent technological advances in laser science, and also in theoretical developments of the Heisenberg-Euler computation, suggest that lasers such as those planned for ELIM may be able to reach this elusive nonperturbative regime. This has the potential to open up an entirely new domain of experiments, with the prospect of fundamental discoveries and practical applications, as are described in many talks in this conference.

II. THE QED EFFECTIVE ACTION

In quantum electrodynamics, the key object that encodes vacuum polarization corrections to classical Maxwell electrodynamics is the “effective action” \( \mathcal{A} \), which is a functional of the applied classical gauge field \( A \). (x) [22,23,24]. The effective action is the relativistic quantum electrodynamics analogue of the grand potential of statistical physics, in the sense that it contains a wealth of information about the quantum system: here, the nonlinear properties of the quantum vacuum. For example, the polarization tensor \( \varepsilon_{ij} = \varepsilon_{ij} \) contains the electric permittivity \( \varepsilon_{ij} \) and the magnetic permeability \( \mu_{ij} \) of the quantum vacuum, and is obtained by varying the effective action \( \mathcal{A} \) with respect...
The general formalism for the QED effective action was developed in a series of papers by Schwinger in the 1950's [22,23]. It is defined in terms of the vacuum-vacuum persistence amplitude

$$h_{out}^i j_{in}^j = \exp \frac{1}{\hbar} f \Re \{ e^{i \phi} \} + i \ln \{ e^{i \phi} \} \tag{2.1}$$

Note that \([A] \) has a real part that describes dispersive effects such as vacuum birefringence, and an imaginary part that describes absorptive effects, such as vacuum pair production. Dispersive effects are discussed in detail in Holger Glaser's contribution to this volume. The imaginary part encodes the probability of vacuum pair production as

$$P_{production} = 1 - \int_{\vec{r}} h_{out}^i j_{in}^j = 1 - \exp \frac{2}{\hbar} \Im \ln \{ e^{i \phi} \} \tag{2.2}$$

Here, in the last [approximate] step we use the fact that \(\Im \{ e^{i \phi} \} = \hbar \) is typically very small. The expression (2.2) can be viewed as the relativistic quantum field theoretic analogue of the well-known quantum mechanical fact that the ionization probability is determined by the imaginary part of the energy of an atomic electron in an applied electric field.

From a computational perspective, the effective action is defined as [22,23,24]

$$[A] = \hbar \ln \det \{ \hat{\mathbf{D}} \hat{\mathbf{m}} \} = \hbar \ln \ln \{ \hat{\mathbf{D}} \hat{\mathbf{m}} \} \quad \tag{2.3}$$

Here, \(\mathbf{D} = \mathbf{D} \) with being the Dirac gamma matrices of relativistic quantum mechanics, and the covariant derivative operator, \(\mathbf{D} = \partial - i \mathbf{A} \), denotes the coupling between electrons and the electromagnetic field \(\mathbf{A} \). When the gauge field \(\mathbf{A} \) is such that the field strength, \(\mathbf{F} = \partial \mathbf{A} \) \(\partial \mathbf{A} \), is constant, the spectral problem becomes that of 2 harmonic oscillators, as is easily seen in the Fock-Schwinger gauge: \(\mathbf{A} = \frac{1}{2} F \times \). In this case, \(\mathbf{F} \) is a 4 × 4 antisymmetric matrix, so its eigenvalues consist of pairs, and can be expressed simply in terms of the two relativistic invariants \(E^2 - B^2\) and \(E \times B\). Then the determinant can be computed in closed form [2,3]. This is like a relativistic analogue of Landau's famous computation of diamagnetism for nonrelativistic electrons in a constant magnetic field [22]. For a constant electric field, of strength \(E\), the result of Heisenberg and Euler is

$$h_{in}^i \equiv \int \frac{e^2 E^2}{8 \pi^2} \frac{1}{s^2} e^{\pi i s} \cot(s) \left( \frac{1}{s} + \frac{s}{3} \right) \tag{2.4}$$

The poles of \(\cot(s)\) lead to an imaginary part of \(\sigma\), whose leading behavior is determined by the first pole at \(s = \) X

$$\frac{\Im}{\Vol} \equiv \frac{e^2 E^2}{8 \pi^2} \exp \frac{m^2}{eE} \tag{2.5}$$

(we now work in units with \(\hbar = c = 1\)). This result, and its interpretation in terms of vacuum instability, was stated clearly already by Heisenberg and Euler [2], building on earlier ideas of Sauter [16].

There is an interesting interpretation of this result as a virial expansion [26,27,28], in which we write

$$\frac{2}{\hbar} \Im = X n_p \ln(1 - n_p) \quad \tag{2.6}$$

where \(n_p = \exp \frac{eE}{2m} (m^2 + p^2)\) is the mean number of pairs with momentum \(p\) transverse to the direction of the field. The sum is over spin states, and the mean momentum phase space trace becomes: \(\exp \frac{eE}{2m} V V T \hat{r}^{2m} \) \(\hat{r}^{2m} \), in which we recognize the electric field analogue of the familiar Landau-level degeneracy factor. Typically, \(n_p \) is very small, so we can approximate \(\ln(1 - n_p) \approx n_p\), in which case we immediately obtain the leading Heisenberg-Euler result [22]. On the other hand, expanding the logarithm we obtain the full instanton sum of Schwinger [23]

$$\frac{\Im}{\Vol} \equiv \frac{h(eE)^2}{(2 \pi)^3} \sum_{n=1}^{k=1} \frac{1}{k} \exp \frac{k m^2}{eE} \quad \tag{2.7}$$

This instanton sum expression can also be obtained by summing over all the poles at \(s = n\) in (2.4).
This result is for spinor QED. If we were to consider the quantized charged particle to be a scalar particle, or even to have classical statistics, then the analogous expressions would be:

\[
\frac{2}{\hbar} \text{Im} = \begin{cases} 
\text{Fermi} & \text{if } E < \text{Fermi} \\
\text{Bose} & \text{if } E > \text{Bose} \\
\text{Boltzmann} & \text{if } E < \text{Bose}
\end{cases}
\]

Thus, when \( n_p \) is small, the leading term is independent of statistics (apart from a simple degeneracy factor \((2s + 1)\)) and so many computations work with scalar QED rather than spinor QED, since it is notationally simpler. But we should remember that \( \frac{2}{\hbar} \text{Im} \) is an approximation. The higher order terms in the sum (2.7) correspond to the coherent production of multiple pairs \( [26,27,28] \) in the same space-time volume \( i \), and quantum statistics effects become important. It would be very interesting if these higher order correlations could be probed experimentally, but at present we are concentrating on being able to measure directly the first term.

### III. BEYOND THE CONSTANT FIELD APPROXIMATION: ONE-DIMENSIONAL INHOMOGENEITIES

So far, we have discussed the theoretical computation of the vacuum pair production probability only in the approximation of a constant and uniform applied electric field. But to reach the nonperturbative regime of \( \mathbf{E} \), for example with ELI, will involve intense, short-pulse, focused laser beams. Therefore, we need to understand how the Heisenberg-Euler result (2.5) for \( \text{Im} [A] \) is modified for gauge \( \mathbf{A}(x) \) corresponding to realistic laser fields with strong spatial and temporal inhomogeneities, as depicted in Figure 2. This is a well-posed problem for which the required formalism exists \( [22,23,29] \), in terms of determinants of the Dirac operator. It is nevertheless a very difficult computational problem for which there are few quantitative results. A somewhat analogous situation exists in the theory of the Casimir effect, as sketched in Figure 3. Casimir's original computation \( [15] \) for a configuration of two parallel plane perfect mirrors leads to a simple expression for the Casimir energy and force, but for more realistic experimentally realizable surface configurations, the computation is well-defined and easily posed, but it is extremely difficult to obtain explicit quantitative results \( [15] \).

**FIG. 2:** Progression from Heisenberg and Euler's original computation of a uniform constant electric field, to more realistic configurations with one-dimensional inhomogeneities, and eventually to realistic focused laser pulses. Here, non-perturbative aspects of vacuum polarization are probed by the externally imposed electromagnetic fields.

**FIG. 3:** Progression from Casimir's original computation of perfect parallel plates, to realistic experimental configurations with different geometries and in perfect surfaces. Here, vacuum polarization is probed by the externally imposed boundaries.
A. The Keldysh approach

As a first step in this direction of computing the vacuum pair production probability in inhomogeneous external elds, recall once again the analogy between vacuum pair production and atom ionization. In the context of atom ionization, Keldysh [30] considered a monochromatic time dependent electric eld represented by the sinusoidal function

\[ E(t) = \frac{E}{2m} \cos(\omega t) \]

For an atom with binding energy \( E_b \), the peak electric eld amplitude \( E_b \) defines a frequency scale \( \omega = \frac{E}{2m} \), and Keldysh identi ed two important physical regimes characterized by the "Keldysh adiabaticity parameter"

\[ \frac{1}{\omega K} = \frac{E_b}{4m} \frac{1}{E} \]

The region \( K = 1 \) is an instantaneous, tunneling, nonperturbative regime, while the opposite limit where \( K \to 0 \) turns out to be a perturbative multi-photon regime. Note that both regions, small and large \( K \), can be spanned without violating the relevant approximations:

\[ \begin{align*}
E \quad E^{\text{ionization}} & \quad \frac{p}{2m} E_b^{3/2} \frac{1}{E} \quad \text{[weak eld approximation]} \\
\h! & \quad E_b \quad \text{[classical eld approximation]} 
\end{align*} \]

In the sinusoidally time dependent electric eld, \( E(t) = E \cos(\omega t) \), Keldysh found the following simple approximate expression for the ionization probability:

\[ P^{\text{ionization}} = \exp \left( \frac{4}{3} \frac{2m}{E_b} \frac{E_b^{3/2}}{E} g\left( \frac{1}{K} \right) \right) \]

The function \( g\left( \frac{1}{K} \right) = 1 \) for \( K = 1 \), while \( g\left( \frac{1}{K} \right) \sim \ln(2K) \) for \( K \to 0 \). Thus, we obtain the limiting behaviors:

\[ P^{\text{ionization}} < \exp \left( \frac{4}{3} \frac{2m}{E_b} \frac{E_b^{3/2}}{E} g\left( \frac{1}{K} \right) \right) \quad ; \quad K \to 0 \] (perturbative)

\[ P^{\text{ionization}} \sim 2 \left( \frac{m}{2} \frac{E}{E_b} \right) \quad ; \quad K \to 0 \] (perturbative)

For small \( K \) the eld \( E(t) \) is essentially constant over the time scale \( 1 = \omega K \), and the ionization process is a nonperturbative tunneling eld, as in Oppenheimer's result [33]. On the other hand, for large \( K \) it is a perturbative multi-photon eld, which can be seen from the fact that in this case the probability is given by the non-adiabatic perturbing eld \( E \) raised to a power equal to \( \omega \) the number of photons required to reach the binding energy. Keldysh's work was developed further by several authors [31,33,34], and the resulting theory to describe strong-eld ionization in atom ic and molecular systems is commonly referred to as the "ADK" theory [35] (see also [36]).

However, in inhomogeneous external elds it is not necessary realistic to neglect the magnetic component of the laser eld [37], so that the representation of the laser eld by just a sinusoidally dependent electric eld \( E(t) \) should be extended. We refer to this comment below, in Section IV.

The Keldysh approach has been adapted to the QED vacuum pair production problem [33,33,40], once again with the laser eld modeled by an oscillating electric eld \( E(t) = E \cos(\omega t) \), and with the role of the binding energy \( E_b \) played by \( 2mc^2 \). The frequency scale set by the peak electric eld amplitude is \( \omega_{\text{QED}} = \omega = (mc)_E \), and the analogous "adiabaticity parameter" is

\[ \frac{1}{\omega_{\text{QED}}} = \frac{m c!}{e E} \quad ; \quad a_0 = \frac{E}{mc!} \]

Here we note that we can also express the adiabaticity parameter as the inverse of the "normalized eld strength" parameter

\[ a_0 = \frac{E}{mc!} \quad ; \quad \frac{1}{a_0} = \frac{mc!}{E} \]

The parameter \( a_0 \) provides a familiar characterization of the laser intensity in the laser and plasma physics literature. Using WKB techniques, one nds [33,33,40], analogous to [33],

\[ P^{\text{pair prod}} \sim \exp \left( \frac{a_0^2}{2} \right) \quad ; \quad 1 \quad \text{(perturbative)} \]

\[ P^{\text{pair prod}} \sim \exp \left( \frac{a_0^2}{2} \right) \quad ; \quad 1 \quad \text{(perturbative)} \]
In the perturbative multi-photon regime, this QED pair production effect has been observed in a beautiful experiment (E-144) at SLAC [43], in which a laser pulse collided with the (highly relativistic) SLAC electron beam, leading to nonlinear Compton scattering involving 5 photons, producing a high energy gamma photon that decays into an electron-positron pair. An important challenge for the ELI project will be to observe pair production in the non-perturbative regime, and directly from vacuum, as a projected goal of ELI [1] is to attain an adiabaticity parameter ε = 10000. Theoretically, this requires reliable predictions of pair production rates and spectra in this non-perturbative regime, for specific ELI laser parameters. Before discussing new work in this direction, I review various approaches that have been developed to analyze the case of external eld that is inhomogeneous in one direction.

B. The one-dimensional scattering picture

An important perspective on vacuum pair production in electric elds with a one-dimensional inhomogeneity is obtained by viewing the problem as a one-dimensional quantum mechanical scattering problem (Popov [44] and Perelomov and Zel'dovich [33] each attribute this idea in this context to L. Pitaevskii). This QM scattering problem can then be solved exactly in some cases, numerically in most cases, or semiclassically by various WKB approaches. Consider a time-dependent electric eld represented by the vector potential A\(_3\)(t), so that E\(_3\)(t) = A\(_3\)(t). As mentioned above, for the leading contribution to the pair production probability we can simplify matters by working with scalar QED, so we write the Klein-Gordon equation (D\(^2\)D + m\(^2\)) = 0 for the eld operator as

\[ (p^2 + eA_3(t))^2 = (m^2 + p^2) \]

(3.7)

This can be viewed as a one-dimensional quantum mechanical Schrödinger equation, with t playing the usual role of x. To describe the process of pair production, we seek solutions of (3.7) with just positive frequencies in the far future, but a mixture of positive and negative frequencies as t → 1:

![Diagram](image)

FIG. 4: The Bogoliubov transformation between in and out states at t = 1, with boundary conditions in [33], can be viewed as a one-dimensional quantum mechanical scattering problem.

In the QM picture, this looks like a scattering problem, and the Bogoliubov transformation between t = 1 modes is encoded in the reaction amplitude \(\Psi\). Since the "potential", \(eA_3(t)\), is negative, and the "energy", \((m^2 + p^2)\), is positive, this is the case of over-the-barrier scattering [44], and so the reaction amplitude \(\Psi\) is expected to be exponentially small. By familiar manipulations [33, 35, 40, 42], the pair production probability is given by

\[ P = \frac{Z}{\sqrt{2 \pi m}} \int d^3p \frac{H p}{m^2 + p^2 + |p|^2 eA_3(t)} dt \]

(3.9)

The dominant exponential contribution can be extracted by setting \(p = 0\), while the prefactor comes from Gaussian integration in the momentum, after expanding the integral in the exponent to quadratic order in momentum. The transverse and longitudinal modes contribute differently, and one arrives at a simple compact formula [33]:

\[ I_{MNKB} = \frac{V_0}{32} \int \frac{p^3 |eE|^{s+2}}{32 \pi m!} \exp \left[ -\frac{m^2}{4p^2} g(2) \right] \frac{d}{dt} \left( \frac{1}{2} g(2) \right) \left. \frac{d}{dt} \left( \frac{2}{2} g(2) \right) \right| \]

(3.10)
Here the function $g(\Delta^2)$ is analogous to the function $g(\kappa)$ appearing in Kelisky's expression \[33\). An explicit formula for $g$ is:

$$
g(\Delta^2) = \frac{Z}{2} \int \frac{dy}{1 + \frac{P}{1 - 2 \gamma^2}}$$

(3.11)

where we have written the imaginary time version of the gauge potential as $\bar{f}(it)$, denoted $y = f = \gamma$, and it is understood that $f^0$ is written back in terms of $y$. For example, for the cosine field $E(t) = E \cos(it)$, we have $A_3(t) = \frac{E}{\gamma} \sin(it)$, and so $g(x_4) = \sinh(!x_4)$. Thus, with $y = f = \gamma$, we have $f^0 = \cosh(!x_4) = \frac{P}{1 + 2\gamma^2}$, and so

$$
g(\Delta^2) = \frac{4P}{1 + 2\gamma^2} K \left[ \frac{2}{1 + \frac{P}{1 + 2\gamma^2}} \right]$$

(3.12)

Here $K$ and $E$ are the standard complete elliptic integrals. The result in (3.12) explains the tunneling and multiphoton limit its quoted in (3.3). Notice that in the WKB formula (3.10), the exponent and the prefactor are both expressed in terms of the same function $g(\Delta^2)$. This result is typically obtained in the imaginary time method of WKB [33,44], but can also be found in conventional WKB [44], and in the phase integral method [44], where higher order WKB contributions have also been considered. A similar form also exists for static electric fields that depend on one spatial coordinate, represented for example by the gauge field $A_3(x_4)$ \[43,44,46\]. It is useful to compare these semi-classical results with some exact results \[45,46\] that arise for the cases $E(t) = E \sech^2(it)$ or $E(x_4) = E \sech^2(kx_4)$. For these fields, the associated Klein-Gordon equation is a soluble Schrödinger problem and so the effective action can be computed in closed form. (In fact, the associated Dirac equations are also exactly soluble). The semi-classical results compare very well with these exact results in the semi-classical regime \[44,47\]. For example, using the phase integral method, for the solvable cases $E(t) = E \sech^2(it)$ or $E(x_4) = E \sech^2(kx_4)$, respectively, the particle number can be expressed as \[44\]

$$\begin{align*}
N & \approx \frac{2\pi}{\hbar} \int_0^1 dp \left[ \frac{1}{1 + \frac{P}{1 - 2\gamma^2}} \right] \\
& \approx \frac{2\pi}{\hbar} \int_0^1 dp \left[ \frac{1}{1 + \frac{P}{1 - 2\gamma^2}} \right]
\end{align*}$$

(3.13)

where in the first expression $\frac{2\pi}{\hbar}$, while in the second expression $\frac{2\pi}{\hbar}$. When the gamma factors go to 0 we recover the form of the constant H eisenberg-Euler result, as is explained in detail in \[44\]. These results illustrate an important point: a term proportional to $\hbar^2$ tends to enhance particle production, while a spatial inhomogeneity tends to suppress particle production. This follows from the different behaviors in the above formulas of the exponents and of the prefactors. Physically, this can be understood as follows: with a spatially inhomogeneous field, the dominant interaction of the field is to make the virtual particles then accelerated apart, away from this point, and if the field falls off too quickly then they may not gain enough energy to become real particles, so that the pair production is suppressed. This effect is seen clearly in the vanishing of the particle number when $\gamma \approx 1$. On the other hand, with a time-dependent field we can regard this as a tunneling problem with an oscillating barrier, for which the tunneling is enhanced roughly speaking because the average barrier is lower \[33,44\].

C. Quantum Kinetic Approach

Another widely-studied approach in the analysis of the time-dependent electric field case, $E = E(t)$, is the quantum kinetic approach \[48,53,58,59,62\]. The key quantity in this formalism is the momentum distribution function, $N(p,t)$, of pairs at a time $t$, which satisfies a quantum Vlasov equation (here for spinor QED):

$$
\frac{dN}{dt} = \frac{e^2}{2} \left( m^2 + p^2 \right)^2 \int \frac{E(t)}{1 + \frac{p^2}{m^2}} \frac{d\gamma}{2} \frac{E(\gamma)}{1 + \frac{p^2}{m^2}} (1 + 2N(\gamma)) \cos 2 \gamma dt$$

(3.14)

Here we have defined

$$!^2 (t) = m^2 + p^2 + (\bar{A}_3(t))^2$$

(3.15)
For scalar QED the analogous quantum Vlasov equation is:

\[
\frac{dN^\infty}{dt} = \frac{1}{2!} \langle t \rangle Z^t \left. \frac{1}{t^c} \right|_{t^c = 0} \langle t \rangle \left( 1 + 2N^\infty \langle t \rangle \right) \cos \frac{Z^t}{t^c} \langle t \rangle \rangle \quad (3.15)
\]

The asymptotic large-time value of \(N\) (\(\langle z; t \rangle\)) gives the momentum distribution of the produced pairs. Note that since the field is spatially uniform we can label the produced pairs by their momenta. The total particle number is obtained by integrating \(N\) (\(\langle z; t \rangle\)) over the momenta. The form of these quantum kinetic equations shows that the process is inherently non-Markovian and non-local in time \([33]\). Furthermore, back-reaction effects have been studied in this approach \([54]\), showing that they are negligible if the maximum amplitude of the electric field is lower than the critical value \(E_c\).

It is not as widely appreciated that the quantum kinetic approach is equivalent to the Popov/Pitaevskii one dimensional scattering approach described in the previous section \([24]\). We illustrate this briefly here for scalar QED. Recall that we can write the Klein-Gordon equation \([3.1]\) as:

\[ + i \frac{\partial}{\partial t} \langle z; t \rangle = 0 \quad (3.16) \]

and convert this Schrödinger-like scattering problem into a Riccati equation as follows \([40]\). First, express the complex field as:

\[
\hat{A} = e^{i' + \frac{\Re e'}{2!}} \langle t \rangle \quad (3.17)
\]

in terms of two other complex fields \(R\) and \(A\) where:

\[
\frac{\hat{A}}{A} = \frac{\Re e^{i'}}{e^{i' + \Re e'}} \quad (3.18)
\]

Then:

\[
- = i' A e^{i'} \Re e' \quad (3.19)
\]

and the scattering equation \([3.17]\) becomes a Riccati equation for the scattering amplitude \(R\):

\[
R = \frac{1}{2!} e^{2i'} \Re^2 e^{2i'} \quad (3.20)
\]

It is straightforward to integrate this equation numerically, with initial condition \(R(1) = 0\), and obtain the probability for particle production as \(R(\approx 1)\). Since \([3.17]\) has the form of a Schrödinger scattering problem with an inverted potential, this is the case of over-the-barrier scattering, which is conveniently analyzed with the method of imaginary time \([25]\). On the other hand, it could just as well be solved "exactly", by numerical integration.

The connection with the quantum kinetic approach is seen by noting that in the quantum kinetic approach [for scalar QED], one writes the field in terms of two other complex fields and:

\[
\frac{\hat{A}}{A} = \frac{1}{2!} e^{i'} + \frac{\Re e'}{2!} \quad (3.21)
\]

The second equation requires to be related by:

\[
- = \frac{1}{2!} e^{2i'} \quad (3.22)
\]

Comparing the two decomposition \([3.16]\) and \([3.21]\) we see that \(R = 1\), and the equations for \(R\) and \(N^\infty\) are then equivalent to the Riccati equation \([3.20]\). The particle number is:

\[
N^\infty = j \frac{\hat{f}}{1 + \frac{\hat{f}}{R \hat{f}}} \quad (3.23)
\]

using the scalar relation: \(j \hat{f} = j \hat{f} = 1\). Converting the Riccati equation for the scattering amplitude \(R\) into an equation just for the probability \(R \hat{f}\), one notes that it is in fact completely equivalent to the quantum Vlasov equation \([3.15]\) of scalar QED \([54]\). Thus, the quantum kinetic approach may be viewed as a real-time version of Popov's in imaginary-time scattering problem. This can also be described equivalently in terms of Green's functions and the S-matrix \([54]\), or in a Schrödinger picture \([57]\).
D. Pulse shaping

In going beyond the constant electric field approximation, the goal is to understand how inhomogeneities modify the constant electric field result [13], so that one might design a pulse shape that leads to a higher yield of vacuum pair production, at a lower peak electric field intensity. The importance of pulse shape for these processes has been studied widely [52,53], and re ects experience gained in the strong-electric field regime of molecular physics community, where sophisticated pulse-engineering techniques have been developed for ionization processes [54,55].

In several recent papers [62], estimates based on taking the electric field pulse(s), neglecting the spatial variation in the focus or the interaction region, suggest that the intensity at which one could see the nonperturbative e ects of vacuum pair production could be a factor of 100 smaller than the critical intensity \( I_c = 4 \times 10^9 \text{ W} / \text{cm}^2 \). This is once again reminiscent of the situation for atomic ionization, where ionization e ects can be observed at intensities lower than the critical electric field estimate of \( 10^{15} \text{ W} / \text{cm}^2 \) coming from Openheimer's constant electric field result [54]. In the QED vacuum polarization problem, with focussed laser pulses, the electric polarization plays an important role [62], but the essential enhancement mechanism is that the interaction region is very large compared to the scale of the Compton wavelength, and so there is a signi cant prefactor enhancement. In these papers, the authors work with an external electric field that is an exact solution of Maxwell's equations, and that in its a Gaussian laser beam; they then convolve this solution with a pulse time envelope function to obtain an approximate solution that represents a focussed laser pulse. In the vicinity of the focus spot, they argue that the spatial dependence can be neglected, so that in the end the problem becomes essentially one-dimensional, and the semiclassical results can be used. An important feature of this approach is that the role of the polarization of the electric ﬁeld is clearly incorporated, and the cases of a single focussed beam, and of two counter-propagating beams were analyzed. The case of two counter-propagating circularly polarized beams leads to a higher yield of produced pairs, and the threshold intensity at which one might expect to see such e ects is several orders of magnitude lower than the Schwinger limit. This is encouraging new avenues for E.L.I.

In a related development, it has recently been shown that the superposition of two time-dependent electric fields can lead to a signi cant enhancement of vacuum pair production, a "dynamically assisted Schwinger mechanism" [63]. The speci c example studied in [63] consists of a combination of a strong but slow electric pulse, and a weak but fast electric pulse:

\[
\begin{align*}
E_{\text{slow}}(t) &= E \text{sech}^2\left( \frac{t}{\tau} \right) \\
E_{\text{fast}}(t) &= E \text{sech}^2\left( \frac{\tau}{t} \right)
\end{align*}
\]

The parameters fall into the hierarchies:

\[
0 < E \lesssim E_c
\]

\[
0 < \tau \ll \tau_c
\]

Surprisingly, even though both electric amplitudes, \( E \) and \( \tau \), are below the critical electric field \( E_c \) in (1.1), there is a signi cant enhancement of the pair production rate when the frequencies are also related as in (3.24). The non-perturbative pair production process that we would associate with the slow strong electric ﬁeld interacts with the perturbative multiphoton pair production process that we would associate with the fast weaker electric ﬁeld to produce a stronger in point than each process separately. This illustrates another possible approach to shaping the laser pulses in the time domain so as to enhance the pair production yield.

IV. TOWARDS MORE GENERAL LASER FIELDS

From a theoretical point of view, as well as from a practical experimental point of view, we should ask if we can go beyond the restriction to a one-dimensional electric field inhomogeneity discussed in the previous section. There are several urgent reasons for studying more general background electric ﬁelds. First, such electric ﬁelds are needed to model more realistic the intense, focussed, short-pulse laser electric ﬁelds to be produced at E.L.I. Second, in the ultra-relativistic regime of E.L.I. it is by no means clear that one can continue to neglect the magnetic component of the laser electric ﬁeld and consider just the electric component. These questions need to be answered.

In fact, surprisingly little is known about vacuum pair production in external electric ﬁelds that have a more complicated inhomogeneity structure, such as appears in a more realistic electric ﬁeld. The results of all the Q.E.D. work summarized in the previous sections is that when the background electric ﬁeld is approximately an electric ﬁeld pointing in one fixed direction, but with amplitude that either (i) varies with time or (ii) varies with space only along the direction of the electric ﬁeld, then the problem can be reduced to a one-dimensional problem that can be solved numerically, or approximately with WKB. However, all these standard approaches become practically intractable when the electric ﬁeld depends on more than one coordinate. An interesting exception is for electric ﬁelds that depend on a light-cone coordinate \( x = ct \) [54,55].
A. Workline form alism for the effective action

It is possible to develop semi-classical approximations for the case of multi-dimensional inhomogeneities in the external field, using Feynman’s workline form alism of the effective action. Feynman’s [66] form ulate a rst-quantized form of QED, which amounts to representing [63, 64] the eective action as a quantum mechanical path integral over closed loops \( x(\cdot) \) in four dimensional space-time, with the closed loops being parametrized by the proper time. As Feynman noted, this proper-time representation is the natural representation for infinitesimal invariance. The proper-time parametrization had been developed earlier by Fock and Nambo [63], and was also used by Schwinger, in operator form rather than in path integral form, in his landmark QED computation of vacuum pair production [23]. Feynman’s workline path integral form alism has since been extended signi cantly, primarily for applications in perturbative quantum eld theory [63], building on analogies and motivation from the Polyakov formulation of string theory. This rebirth has led to many beautiful advances in our understanding of perturbative scattering amplitudes [71], but here I propose to use it instead to extract non-perturbative information. Let us consider scalar QED rather than spinor QED, as it is notationally simpler, and the leading in the part of the eective action only differ from that of spinor QED by a spin degeneracy factor of 2. Then the eective action for a scalar charged particle (charge \( e, \text{mass } m \)) in a Euclidean classical gauge background \( A(x) \) is the functional:

\[
[A] = \text{tr} \ln \left( \int_0^T e^{-D^2 + m^2 \tau} \right)
\]

This explains the second line in (4.1), where we have performed the trace in the position representation. The last line in (4.1) follows from interpreting the matrix element \( \langle x(\cdot) \rangle \) as a Euclidean transition amplitude, which is then written using Feynman’s representation as a path integral, but now involving paths \( x \) in four dimensional space-time. Since for the eective action we compute the trace of the logarithm, the matrix element is between identical points \( x(0) \), and so the path integral is over closed loops. Thus, we arrive at a rst-quantized representation of the eective action \( [A] \) in terms of a functional integral \( D x \) over all closed Euclidean space-time paths \( x(\cdot) \) that are periodic with period \( T \) in the proper-time parameter \( \tau \). I use the QED workline path integral normalization conventions of [69]. Note also that we have expressed the path integral in Euclidean space, as is appropriate for describing a non-perturbative process.

This representation of the eective action translates the primary computational problem into one of computing the quantum mechanical path integral in the last line of (4.1). This simple observation has several advantages. First, one could evaluate this Euclidean path integral numerically, using the workline Monte Carlo technique of Gies and Langfeld [72]. One creates a statistical ensemble of configurations, namely a set of closed loops \( x(\cdot) \) in 4-dimensional Euclidean space-time, weighted by a factor \( \exp \left[ -\int_0^T e^{-D^2} \right] \), and then one computes numerically, using a Monte Carlo algorithm, the expectation of the "W ison loop" operator \( \mathcal{O} \). For the path production problem, the exponentially small imaginary part, arising from poles in the \( T \) integral, can then be extracted numerically. This is still a challenging numerical problem, but it has been shown to work well for situations with one-dimensional inhomogeneities of the electric field [73]. This is potentially a very powerful approach, as it does not rely on any particular symmetry of the background field (the ensemble of closed space-time loops used in the numerical Monte Carlo evaluation of the quantum mechanical path integral is independent of the background field). Physically, the ensemble probes the structure and in the part of the background field. This means that in principle the numerical workline Monte Carlo approach can be used for quite general inhomogeneous laser field configurations. This approach deserves further exploration.

B. Workline Instantons

A second, complementary approach is more analytical: make a semi-classical approximation to the Euclidean workline path integral. The essential idea is that the quantum mechanical path integral may be approximated by the contribution of a single numerical (possibly just one) of classical closed loops, plus the quantum fluctuations about these loops. These dominant Euclidean loops are called "workline instantons". This is the Euclidean space analogue of the familiar semi-classical scattering theory [72, 73], where a real-time scattering process is approximated by classical
trajectories, with corrections from quantum fluctuations about the classical trajectories. The dominance of the path integral by just a few closed paths is a semi-classical approximation, valid when the classical action is large compared to $\hbar$. If the background field has a simple functional form, depending on just a few physical parameters such as peak field amplitude, a frequency or wavenumber, etc., then the regime of the semi-classical approximation can be precisely quantified in terms of a few dimensionless quantities. The idea of seeking dominant semi-classical solutions to the path integral appearing in (4.1) was suggested long ago [74], and was first applied to the vacuum pair-production problem for a constant electric field in [75]. More recently, the idea has been extended to the vacuum pair-production problem with inhomogeneous background fields in various configurations [76, 77, 80, 81]. The special dominant loops are solutions to the associated classical (Euclidean) equations of motion for a charged particle moving in the given inhomogeneous electromagnetic field $\mathbf{F}(x)$:

$$ x = 2 \epsilon \mathbf{F}(x) \mathbf{x} \quad ; \quad (i = 1, \ldots, 4) \quad ; \quad (4.2) $$

Solutions of the classical Euclidean equations of motion (4.2) that are closed and periodic are called worldline instantons.

For example, for a constant (Minkowski) electric field $E_3 = E$, the Euler-Lagrange equations of motion in Minkowski space, with the coordinates $x$ (s) parametrized by proper time $s$ are (here the overdot $\dot{}$ refers to $\frac{ds}{ds}$):

$$ x_3 = 2 \epsilon E \mathbf{x} \quad ; \quad t = 2 \epsilon E \mathbf{x} \quad ; \quad (4.3) $$

The solution is well-known:

$$ x_3 = \frac{\cosh (2 \epsilon E s)}{2 \epsilon E} \quad ; \quad t = \frac{\sinh (2 \epsilon E s)}{2 \epsilon E} \quad ; \quad (4.4) $$

In a 1+1 dimensional Minkowski spacetime diagram, these follow open hyperbolic trajectories, as shown in Figure 5. On the other hand, in Euclidean space, with $x_4 = i c t$, and $s = t$, the equations read (here the overdot $\dot{}$ refers to $\frac{dt}{dt}$):

$$ x_3 = 2 \epsilon \mathbf{x} \quad ; \quad x_4 = 2 \epsilon \mathbf{x}_3 \quad ; \quad (4.5) $$

and the solutions describe closed circular orbits, as shown in Figure 6:

$$ x_3 = \frac{\cos (2 \epsilon E s)}{2 \epsilon E} \quad ; \quad x_4 = \frac{\sin (2 \epsilon E s)}{2 \epsilon E} \quad ; \quad (4.6) $$

For a time dependent (Minkowski) pulse field, given by $E_3(t) = E \text{sech}^2(\pi t)$, the Minkowski equations are:

$$ x_3 = 2 \epsilon E \text{sech}^2(\pi t) \mathbf{x} \quad ; \quad t = 2 \epsilon E \text{sech}^2(\pi t) \mathbf{x}_3 \quad ; \quad (4.7) $$

FIG 5: The Minkowski space-time trajectories of a charged particle in a constant electric field. The analogy with the trajectory of an accelerated observer is the starting point for the discussion of the Unruh effect in strong electric laser systems (see R. Schutzhold's article in this Volume.)
The Euclidean space-time trajectories [both directions around the loop] of a charged particle in a constant electric field. The open trajectories in Minkowski space, shown in Figure 5, are now closed trajectories in Euclidean space. This is the simplest worldline instanton, a periodic solution to the classical Euclidean equations of motion.

The Minkowski solutions are the open trajectories:

\[
\begin{align*}
x_3(s) &= \frac{1}{\sqrt{1 + 2\cosh \frac{2E}{1 + 2s}}} \ \text{arcsinh} \ \cosh \frac{2E}{1 + 2s} i \\
t(s) &= \frac{1}{\sqrt{1 + 2\sinh \frac{2E}{1 + 2s}}} \ \text{arccosh} \ \sinh \frac{2E}{1 + 2s}
\end{align*}
\]

where \( \gamma = \frac{1}{e^E} \). These trajectories are shown in Figure 7. On the other hand, the Euclidean trajectories are closed loops:

\[
\begin{align*}
x_3(\tau) &= \frac{1}{\sqrt{1 + 2\cosh \frac{2E}{1 + 2\tau}}} \ \text{arcsinh} \ \cosh \frac{2E}{1 + 2\tau} i \\
x_4(\tau) &= \frac{1}{\sqrt{1 + 2\sinh \frac{2E}{1 + 2\tau}}} \ \text{arccosh} \ \sinh \frac{2E}{1 + 2\tau}
\end{align*}
\]

and are shown in Figure 8.

Expanding in the fluctuations about the worldline instanton loop, \( x(\tau) = x_{\text{cl}}(\tau) + \ldots \), we obtain an approximate expression for the path integral:

\[
Z \approx \int \mathcal{D}x e^{-S[x]} e^{S[x_{\text{cl}}]} D \exp \left[ \frac{1}{2} \int_0^T d\tau \right]
\]
Figure 8: The Euclidean space-time trajectories (both directions around the loop) of a charged particle in an electric field pulse, $E(t) = E_0 \text{sech}^2(\frac{t}{\tau})$, with adiabaticity parameter $\tau = 2$. For reference, the dotted line shows the corresponding circular trajectory in a constant field where $\tau = 0$. The open trajectories in Minkowski space are now closed trajectories in Euclidean space. This is the simplest worldline instanton, a periodic solution to the classical Euclidean equations of motion.

$$\det (\cdot) = e^{S[x^c]} \text{det} ;$$

(4.10)

where $S[x^c]$ is the classical action, evaluated on the worldline instanton loop. The prefactor is expressed in terms of the determinant of the fluctuation operator (the "Jacobian operator") is

$$\frac{1}{2} \frac{d^2}{d^2} + eF(x^c) \frac{d^2}{d^2} + e\theta F(x^c) \phi^2 :$$

(4.11)

In [78] it was shown that the worldline instanton exponential factor $e^{S[x^c]}$ agrees precisely with the WKB exponential factor $\exp \left[ \frac{i}{\hbar} g(\varphi) \right]$ in (3.10), for the case of one-dimensional inhomogeneities.

The form of the fluctuation operator in (4.11) exhibits another major advantage of the worldline approach (since the paths are parametrized by proper time, the fluctuation problem refers to a one-dimensional operator (actually, coupled one-dimensional operators) rather than a partial differential operator in four-dimensional spacetime. This is technically important because there are simple mathematical methods for computing the determinant of such one-dimensional operators [72,74,83,84], but these techniques do not generalize easily to partial differential operators. Thus one can numerically compute $\det(\cdot)$ for any period $T$, and then perform the remaining $T$ and $x^{(5)}$ integrals in the effective action expression (4.1). In fact, in [72] it was shown that for one-dimensional inhomogeneities the determinant of the fluctuation operator can be computed analytically:

$$\det (\cdot) = 2m x_2^c(T) \int_0^{Z(T)} \frac{dx}{x_2^c(x)}$$

(4.12)

Further, after doing the $T$ integral by steepest descents, one reproduces exactly the WKB result (4.1), including the prefactor term [72].

This agreement with previous one-dimensional classical results is encouraging, but the real advantage of the worldline instanton method is that it can be extended to more general fields. Technically, there are several steps to the computation: (i) nd periodic solutions (the worldline instantons) to the Euclidean classical equations of motion (3.4); (ii) The domain instanton exponential factor in the pair production rate is $\exp[S[x^c]]$, involving the classical action evaluated on the worldline instanton path; (iii) The prefactor coming from the semiclassical approximation to the quantum mechanical path integral is given by the determinant of the fluctuation operator in (4.11), evaluated on the worldline instanton path; (iv) The $T$ integration gives the conserved quantity $\frac{1}{2} x_2^c$ to take the value $m^2$, and also produces a prefactor; (v) Possible residual dependence on the spacetime location of the loop must be integrated over. In a Gaussian approximation this also leads to another prefactor.
C. Worldline Instantons and the Gutzwiller Trace Formula

Note that in general there are three apparently separate [but below we shall see that they are in fact related!] prefactor contributions to the nal answer: one coming from each integration in (4.14). This procedure is reminiscent of that used to derive the Gutzwiller trace formula [85, 86, 87] for the trace of the Green’s function in non-relativistic quantum mechanics:

\[
\text{tr} G(E) = \frac{Z}{Z_f} \int_0^T dx \frac{dx}{2\pi} \text{det} S_p(E) \text{det}(1 - J_p) \int_0^T dx j_e^{iHt} j_xi
\]

(4.13)

Here \(T_p\) is the period of the classical closed orbit of energy \(E\), \(S_p(E)\) is its action, \(J_p\) is the associated monodromy matrix [see below], and \(m, p\) are Maslov indices. Before proceeding to the corresponding worldline instanton expression, we briefly sketch the strategy of the derivation of the Gutzwiller trace formula [an excellent introduction for physicists is in [83]]. The first step is to make a semi-classical approximation for the propagation kernel in (4.13) between distinct points \(x\) and \(x'\), in a time interval:

\[
hx j_e^{iHt} j_xi = S \text{det}(1 - J) \int_0^T dx j_xi
\]

(4.14)

Here, \(S(x;x',t)\) is Hamilton’s principal function for the path connecting the points \(x\) and \(x'\), in time \(t\). The prefactor is the Van Vleck determinant factor, given by variations with respect to the path’s endpoints. The next step is to evaluate the integral in (4.13) by the stationary phase approximation. Here we note that the exponent is \(\phi = E x + R(x;x',t)\), whose stationary point condition, \(\frac{\partial R}{\partial x} = 0\), gives \(t\) to be the period such that the closed classical path has energy equal to \(E\). This means that the stationary point condition in planar integrals: the Legendre transform from \(R(x;x',t)\) to the action \(S(x;x';E)\) associated with the closed classical orbit of energy \(E\). Further on, the prefactor from the \(t\) integral contributes a factor \(1 = \frac{\partial S}{\partial R} = \frac{\partial R}{\partial x} = \frac{\partial S}{\partial x}\), which follows from the other Legendre transform relation \(\frac{\partial R}{\partial x} = t\). The next step towards the Gutzwiller trace formula (4.14) is to take the coincident point in \(x, x'\) and to integrate over the closed orbit, the beginning and end of the orbit. Evaluating this integral by a third and nailest step action for the closed loop to be periodic. The semi-classical approximation forces the closed loop to be periodic. In the language of quantum field theory, this is a collective coordinate contribution, associated with the zero mode coming from the basic fact from classical mechanics that the fluctuation operator has a zero mode: \(x'^i = 0\). On the other hand, the transverse \(x\) integrations give yet another determinant prefactor \(1 = \text{det} \frac{\partial^2 S}{\partial x_i \partial x_j}\).

The remarkable result of Gutzwiller [85] is that these three different-looking prefactors (coming successively from a semi-classical approximation to the quantum mechanical path integral, the time integral, and finally the \(x\) trace) all combine into a single determinant prefactor that has a simple geometric interpretation in phase space:

\[
\frac{Z}{Z_f} \int_0^T dx \frac{dx}{2\pi} \text{det} S_p(E) \text{det}(1 - J_p) \int_0^T dx j_e^{iHt} j_xi
\]

(4.15)

Here \(J\) is the monodromy matrix of the periodic orbit having energy \(E\) and period \(T_p\). For a precise definition of \(J\) see [83, 86, 87], including the Maslov indices, which we have suppressed here for the sake of simplicity. It is sufficient here to note that the full prefactor is expressed in terms of a classical invariant of the closed orbit, which characterizes the behavior of all deviations from the periodic orbit in phase space.

These steps we have just sketched for the derivation of Gutzwiller’s trace formula are closely analogous to the steps required in evaluating the worldline path integral expression (4.1) for the effective action \(A\). Thus, analogous to (4.14), we seek the following representation of the imaginary part of the effective action:

\[
\text{Im} A = \text{Im} \int_0^T dx \frac{dx}{2\pi} \text{det} S_p(E) \text{det}(1 - J_p) \int_0^T dx j_e^{iHt} j_xi
\]

(4.17)
The effective action [A] in (4.1) involves a Euclidean path integral, in four dimensional space rather than a path integral in three dimensional non-relativistic quantum mechanics. There is also an extra factor of $1-T$ because [A] is a log determinant. Nevertheless, the ideas follow through, and in the end we can combine the three prefactors found by following the worldline instanton strategy enumerated above, to form one single prefactor expressed in terms of the monodromy matrix for the periodic orbit, now viewed in phase space [88]. The successive approximations are

$$K(x;x^0; T) = \hbar x^0 \int \frac{d^4 x}{(2\pi)^4} \frac{e^{-\frac{1}{\hbar} \int_0^T \dot{x}^2 dt}}{\det \frac{\partial^2 R}{\partial x^0 \partial x^0}} e^{R(x;x^0; T)}$$

(4.18)

where $R(x;x^0; T)$ is the Hamilton principal function for the classical trajectory from $x$ to $x^0$ in four dimensional Euclidean space, in the proper-time interval $T$. Next, the $T$ integral is evaluated by steepest descents. The critical point of the exponential factor arises when $\frac{\partial R}{\partial x^0} = m^2$. This has a natural classical interpretation in terms of the Legendre transformation between the Hamilton principal function $R(x;x^0; T)$ expressed in terms of the total time elapsed along the trajectory and the action $S(x;x^0; E)$ expressed in terms of the total energy of the trajectory: $R(x;x^0; T) = S(x;x^0; E) - T E$. Thus, the critical point $T_c$ of the $T$ integral occurs when $E = m^2$, so that

$$Z \int_0^T \frac{dT}{T} e^{-\frac{1}{\hbar} \int_0^T \dot{x}^2 dt} K(x;x^0; T) = \frac{1}{(2\pi)^4 T_c} \frac{e^{-\frac{1}{\hbar} \int_0^T \dot{x}^2 dt}}{\det \frac{\partial^2 R}{\partial x^0 \partial x^0}} e^{\frac{2}{\hbar} \int_0^T \dot{x}^2 dt} e^{S(x;x^0; m^2)}$$

(4.19)

The final step is the coincident limit $\hbar \to 0$! $x^0 = x^{(0)}$, and the trace over $x^{(0)}$, yielding

$$\int e^{S(E=m^2) \frac{1}{\det (L+J)}}$$

(4.20)

The main advantage of expressing the computation in this language of the Gutzwiller trace formula is that the total prefactor is encapsulated in a single determinant, which moreover has a natural interpretation as the geometric meaning in the Euclidean phase space [88]. In previous work [38,33,44,73,80] the various prefactor contributions have been evaluated separately, and then combined at the end. Thus, the computational strategy of the worldline instanton approach can be stated succinctly as follows:

1. solve the classical equations of motion in four dimensional Euclidean space to find all closed periodic trajectories of "energy" $E = \frac{1}{\hbar} m^2$: such a solution is a worldline instanton."
2. evaluate the classical action $S_{cl}(E = m^2)$ on these trajectories. Then the leading exponential contribution to $\text{Im} \ e^{S_{cl}}$.

3. compute the prefactor from the monodromy matrix $J$ for the dominant trajectory(ies).

As an illustration of this procedure, consider again the case of a one-dimensional inhomogeneity, for example, the case of a time dependent electric field directed in the $x_3$ direction. As noted above, for such a configuration the vacuum pair production probability can be computed in several other ways using WKB methods [35,36,44,79], and so it is possible to make a direct comparison. We can choose a Euclidean gauge electric field $A_3(x_4) = P \ f(x_4)$, where $E$ characterizes the overall amplitude of the associated electric field, $f$ characterizes the scale of the time dependence, and $f(x_4)$ is some smooth function. For example, for a constant electric field $E(t) = E$, we have $f(x) = x$; for a sinusoidal electric field $E(t) = E \ \cos(\omega t)$, we have $f(x) = \ \sin(x)$; and for a single-pulse electric field $E(t) = E \ \sech^2(\cosh t)$, we have $f(x) = \ \tan(x)$. Then the classical action on a periodic trajectory of energy $E$ can be written (here $y = \frac{x^E}{E} f(x)$)

$$I = \int_{x_4}^{x_4} dx_4 E \ e^{E f(x_4)}$$

$$S(E) = E \ int \frac{dx_4}{E} f(x)$$

$$= 2E \int_0^1 dy \ \frac{y^2}{E}$$

$$\text{Im} \ e^{S(E)} = \int_{x_4}^{x_4} dx_4 E \ e^{E f(x_4)}$$

(4.21)

Evaluated at $E = m^2$, this is precisely the exponent, $g(\omega^2) m^2 = \text{e}(E)$, appearing in the standard WKB result for the pair production rate [35,36,44,79]. To evaluate the prefactor, we can choose $x_4$ as $x_k$. Then the transverse $x_3$ direction is in fact an invariant "at" direction, so we do not need to perform the transverse integration. This illustrates the important point that (4.20) must be interpreted appropriately when there are physical zero modes associated with symmetries of the electric field. Thus, we go back to (4.19) and observe that $\frac{\partial f}{\partial x_3} = \frac{1}{E} \ f'(x)$. Furthermore, the other determinant factor in (4.19) is easily computed (see [79]) using the Gelfand-Yaglom formula:

$$\text{det} \left[ \frac{\partial^2 \mathbf{R}}{\partial x \partial x^3} \right]_{x=x^0} = \frac{m^4}{16E^3} \ T^2 \ \frac{1}{x_4^2} \ \frac{\partial x_3}{\partial x_3}$$

Thus, relative to the constant spatial volume $V_3$,

$$\text{Im} \ \ e^{S(E)} = \int_{x_4}^{x_4} dx_4 E \ e^{E f(x_4)}$$

(4.22)

(4.23)

Note that (4.22) agrees precisely with the conventional WKB result in [61], with the added semi-classical interpretation of the various terms.

V. CONCLUSIONS

I conclude by reiterating that the ELI project has great promise to open up an entirely new non-perturbative regime of QED, and of quantum field theories in general. There are many experimental and theoretical challenges ahead, but the future appears bright. Theoretically, the biggest challenge in the non-perturbative arena is to develop new ideas and methods are still needed. A more important issue is that back reaction, which is typically ignored in the limit where the electric field strength is below the critical field in (4.1). But the combination of an ELI laser with an accelerated electron beam may produce electric field strengths well above the critical field, in which case back-reaction becomes significant. Insights from these nonperturbative QED studies should have implications for related questions in gravitational systems of quantum field theory in strongly curved spaces, and also for non-perturbative effects in nonabelian gauge theories [33].

Acknowledgments: I thank the organizers of the ELI Frauenwörth conference, especially D. Habs and M. Gross, for an extremely interesting meeting, and I thank G. Mourou and T. Tajima for helpful discussions. I acknowledge
support from the DOE through the grant DE-FG02-92ER40716, and from the European Commission under contract ELIpp 212105 in the frame work of the program FP7 Infrastructures-2007-1.

[90] Note that the factor 2e has nothing to do with Cooper pairs; the factor of 2 is simply a side effect of the standard normalization conventions of worldline path integrals [63], in which the "kinetic" term in (4.1) is $\chi^2=4$, rather than $\chi^2=2$.
