N I C M O S Photometry of the Unusual Dwarf Planet Haumea and its Satellites

W. C. Fraser 1, M. E. Brown 1,

ABSTRACT

We present here HST N I C M O S F110W and F160W observations of Haumea, and its two satellites Hi‘iaka and Namaka. From the measured (F110W - F160W) colours of 1208 0.004, 148 0.06, and 14 0.2 mag for each object, respectively, we infer that the 1.6 m water-ice absorption feature depths on Hi‘iaka and Namaka are at least as deep as that of Haumea. The light-curve of Haumea is detected in both filters, and we find that the infrared colour is bluer by 2.3% at the phase of the red spot. These observations suggest that the satellites of Haumea were formed from the collision that produced the Haumea collisional family.

1. Introduction

The recently named dwarf planet Haumea—from early known as 2003 EL61—is a peculiar Kuiper belt object; it is the primary body of a triple system [Brown et al. 2006], the largest member of the only known Kuiper belt collisional family [Brown et al. 2007], and exhibits deep water-ice absorption which, in the Kuiper belt, has been observed only on the collisional family members, and its largest satellite—Hi‘iaka [Barkume et al. 2006; Schaller & Brown 2008; Barkume et al. 2008].

The small angular extent of the orbit of inner and smaller satellites, Namaka, has made a spectroscopic measure of its reflectance impossible with ground based facilities. The Hubble Space Telescope has sufficient angular resolution to separate Namaka from Haumea (see Figure 1). The F160W filter is sensitive to the 1.6 m water-ice absorption feature. Thus with a measure of the continuum near the water-ice absorption, the depth of the water-ice absorption of Namaka can be inferred from Hubble imaging photometry.

Here we present photometry of the Haumea triple system using the NICMOS camera. With these observations, we clearly separate Haumea, Hi‘iaka, and Namaka, and provide photometry of these objects with the F110W and F160W filters. In Section 2 we describe the observations and describe data reductions we performed. In Section 3 we present our results. We demonstrate that our measurements are consistent with a simple water-ice absorption model for Haumea, and infer the water-ice absorption of its satellites. Finally, we discuss our results in Section 4.

2. Data and Analysis

Observations were made in cycle 16 using NICMOS camera 1 on May 7, 2008 (UT). Images were taken in the F110W and F160W filters with exposure times of 144 and 320 s respectively. Images were taken in pairs with alternating filters, and in a 5-point dither pattern to allow accurate background removal and to avoid hot-pixels in the camera. Because the time between adjacent colour pairs was short compared to the rotation period of Haumea, the images of a pair sampled approximately the same phase of Haumea and its satellites.

The data were initially processed through calhica, the standard HST reduction and calibration procedure [Bushouse 1997]. Residual backgrounds and non-linearities were then removed using the pedsky and mlincoor routines from the STSDAS package. The background of each image did not vary significantly from image to image. Thus, a median image was produced from all for each

We performed aperture photometry on Haumea. An aperture photometry was performed on the satellites using 5-6 pixel radius apertures, after removing the best-t amused scaled tinytim PSF [Krist 1992] of Haumea; we found that while the undistorted tinytim PSF could not accurately model the core of Haumea's image, subtraction of the PSF did remove the wings of Haumea's image to within the image noise near the locations of each satellite. In nine aperture corrections were measured from the image of Haumea and the resultant aperture corrected photometry of each source is presented in Table 1. The uncertainties presented are derived from the statistical error in image extensions provided with the calibrated images and do not include the 5% absolute photometric calibration error or the 2% relative calibration error from the calhica data reductions (see the NICMOS Data Reductions Handbook).

3. Results

Presented in Figure 2 are the average photometry of Haumea and its satellites with solar colours removed. As can be seen from this figure, all three objects exhibit absorbance consistent with water-ice.

3.1. Haumea

We find that Haumea exhibits a mean (F110W - F160W) colour of 1.208 ± 0.004. Barlow et al. (2008) found that the spectrum of Haumea was well described by a mixture of water-ice and a linear blue component. Using their model (Equation 1. from Barlow et al. 2008) and best-

1STSDAS is a product of the Space Telescope Science Institute, which is operated by AURA for NASA.
ters as input to the synphot routine, we reproduce the colour of Haum ea within the uncertainties of our measurements. This modeling demonstrates that from these observations, we find a 40% water-ice absorption depth on Haum ea compatible with the observations of Barkume et al. (2008) and can infer the relative absorptions of the two satellites.

Rabinowitz et al. (2006) found that Haum ea exhibits a double-peaked light-curve with a 3.9 hour rotation period. Lacerta et al. (2008) found that the colour of Haum ea varies and is consistent with a large spot on one face of the dwarf planet which is optically redder than the mean surface colour.

We detected Haum ea’s light-curve in our observations, and found that our observations are consistent in both phase and magnitude with those of Lacerta (2008). The observed (F110W - F160W) exhibits a variation of 0.03 m ag from the mean which is a > 3 deviation compared to the uncertainties in our measurements. The deviation occurs at a light-curve phase 0.78, consistent with the phase centre of the red spot (Lacerta et al. 2008).

The variation we observe is bluer, or 2.3% more negative (F110W - F160W) at the red spot compared to the mean of the surface. The bluer apparent colour could be caused by increased water-ice absorption or larger water-ice grains compared to the mean surface. There is no reason to expect such an association of ice properties with a red visible surface component, however. A more plausible explanation is that the red spot detected by Lacerta et al. (2008) is caused by an increase in the abundance of irradiated organic materials (olons, etc.) on the surface. These materials typically appear blue in the infrared (Khare et al. 1984) and could thus account for the observed effect.

3.2. Hi’iaka

No photometric variation of Hi’iaka was observed to the accuracy of our measurements. Hi’iaka exhibits a deeper absorption than Haum ea with a mean (F110W - F160W) = 1.48 ± 0.06. The observations suggest that the 1σ m water-ice absorption is approximately 30-40% deeper on Hi’iaka than Haum ea which is consistent with the observations of Barkume et al. (2008).

3.3. Namaka

Namaka was found to exhibit a photometric variability of 0.3 m ag in both bands. This variability is slightly larger in amplitude than the measurement uncertainties, but further observations are required to confirm this variability. We did not detect any variability in the absorption on Namaka to within the accuracy of our measurements. Namaka’s absorption is consistent with both that of Haum ea and Hi’iaka, though with larger uncertainties, and is inconsistent with a flat spectrum. The observed mean (F110W - F160W) = 1.4 ± 0.2 suggests that Namaka’s spectrum
exhibits a water-ice absorption depth at least that of Haum ea.

4. Discussion

Assuming similar infrared albedos, the observed mean phase ratios suggest that Haum ea, Hi’aka and Namaka have size ratios 1 : 0.29 : 0.14. The potentially large variability of Namaka suggests it has an elongated shape. This variability however, would be insignificant if the photometric uncertainty quoted here were actually slightly underestimated. Thus, more measurements are required to confirm this variability.

Our findings demonstrate that both Namaka and Hi’aka exhibit the deep water-ice absorption characteristic of Haum ea and its collisional family. If Hi’aka and Namaka were dynamically captured satellites, they would be expected to show colours representative of the entire Kuiper belt population. They however, exhibit the deep water-ice features that are only observed on the family members. The water-ice features exhibited by both satellites suggest that they are made of the icy-mantle material that covers the surface of Haum ea (Brown et al. 2007). We conclude that the satellites are a result of the disruption that created the Haum ea collisional family.

The extremely deep water-ice absorption on Hi’aka is consistent with a blue linear-component in the water-ice mixture approximately twice as steep as that on Haum ea, assuming similar mixture ratios. The deep absorption could also be caused by water-ice grains 2-3 times larger than those observed on Haum ea. The true cause however, cannot be determined from our observations, and warrants further observations and spectral modeling to understand the extremely deep absorption features on this satellite.

5. Acknowledgements

The authors would like to thank Dr. Emily Schaller, and Darren Ragozzine for their very useful discussions of, and suggestions for this project. This material is based upon work supported by NASA under the grant NNG05G02G. Support for program HST-G0-011169.9-A was provided by NASA through a grant from the Space Telescope Science Institute, which is operated by the Association of Universities for Research in Astronomy, Inc., under NASA contract NAS 5-26555.

Table 2. Colour measurements. All measurements do not include the 2% relative or 5% absolute photometric error associated with the NICMOS filters. This uncertainty however, will cause a common offset in the colours for each measurement and the relative differences between measurements will remain constant. Numbers in parenthesis are the rotation phase of Hau maua determined from the published light-curve of Lacerda et al. (2008).

Fig. 1. Example F110W image of Haumea Hi'aka (left) and Namaka (right).
Fig. 2. Model water-ice plus at component spectrum from Barkume et al. (2008) (solid line). Haumea spectrum from Trujillo et al. (2007) (dotted solid). The F110w (dotted) and F160w (dash-dotted) band-passes multiplied by the Solar spectrum are shown. Photometry of Haumea (squares), Hi'aka (circles), and Namaka (triangles) are presented. Solar colours have been removed, and the measurements have been scaled to have equal relative flux in the F110w band. Data for Hi'aka and Namaka have been horizontally offset for clarity. Error-bars are only the photometric shot-noise, and do not include the relative or absolute photometric errors associated with the NICMOS filters.
