We measure the evolution of the coupling constant using the Schrödinger functional method in the lattice formulation of SU (2) gauge theory with two massless Dirac fermions in the adjoint representation. We observe strong evidence for an infrared fixed point, where the theory becomes conformal. We measure the $\kappa$-function and the coupling constant as a function of the energy scale.

I. INTRODUCTION

In preparation for the phenomenology at LHC, there has recently been increased interest in QCD theories which appear (quasi) conformal when probed towards infrared, i.e., over large distance scales. There are basically two novel frameworks which utilize such theories, namely, walking technicolor [1] and unparticles [2,3]. For models building along these directions it is very desirable to single out candidate theories which allow for the existence of a nontrivial infrared fixed point and then use these as a basis for more detailed analyses. To determine the location of the conformal window as a function of the number of colors, avors and fermion representations is a non-perturbative problem. Traditional way to obtain semiquantitative estimates is the so-called rainbow approximation to the Schrödinger-Dyson equation for the nonperturbative fermion propagator [4,5,6]. More recent developments include analytic $\kappa$-function ansatzes [7,8,9] and analyses on the role of topological excitations [10]. Phenomenological constraints on walking technicolor require that conformal behavior is obtained with only modest amounts of new matter fields, and utilizing higher representation fermions, several plausible candidates have been proposed in [11,12]. Although subject to uncertainties, these methods are invaluable in providing hints towards theories which are of phenomenological interest and motivate their analyses using lattice methods.

Guided by the phase diagrams of [11], initial lattice studies of two and three color theories with two fermion flavors in the two-index symmetric representation have recently appeared [13,14,15,16,17,18]. For related studies with fundamental fermions in SU (3) gauge theory, see [19,20,21,22,23].

In this work we study the evolution of the coupling constant of the candidate model with $n_{\text{ini}}=1$ field content, consisting of the standard SU (2) gauge fields and two massless Dirac fermions in the adjoint representation. The euclidean Lagrange density is

$$L = \frac{1}{2} \text{Tr} F^2 + P^\dagger \kappa D \kappa - f$$

with $D = \kappa + ig A \kappa^T$, where $(\kappa^T)^{ab} = i \kappa^{abc}$ are the generators of the adjoint representation. To obtain the evolution of the coupling we use the lattice Schrödinger functional scheme, which has been very successfully applied to e.g., two-avour QCD by the Alpha collaboration [24].

Perturbatively, the two-loop $\kappa$-function of this theory with $N_f$ adjoint fermions is

$$(\kappa) = \frac{dg}{d\kappa} = -\frac{g^3}{16\pi} + \frac{T_3}{16\pi^2} - f$$

where $0 = (22, 8N_f)$ and $1 = (34, 32N_f)$. For $N_f = 1$ the coe cient $0$ is positive while $1$ is positive for $N_f = 1$ but negative for $N_f = 2$. Hence, for $N_f = 2$ there is a zero of the two-loop $\kappa$-function at $g^2 = (0 = 1) 16^{-2} 72$, i.e., $g^2 = (4) 0.5$, corresponding to an infrared fixed point. Large value of $g^2$ casts doubt on the validity of the perturbative result and nonperturbative measurement of the running coupling on the lattice is required. Indeed, as we report below, the lattice simulations reveal large deviations from the two-loop perturbative behaviour.

We note that the $\kappa$-function has been calculated up to four loops in the Minimal Subtraction (MS) scheme [25]. Beyond two loops the $\kappa$-function is scheme dependent and the result cannot be directly compared with the lattice Schrödinger functional scheme used here.

For the gauge group SU (2) considered here the two-index symmetric representation coincides with the adjoint representation. We have recently performed large-volume high-statistics lattice simulations of this theory, concentrating on the chiral properties of the mass spectrum [26,27]. The main result of this study was that at small enough lattice gauge coupling, in contrast to
where we did not observe spontaneous chiral symmetry breaking as the quark mass was increased. Because the chiral condensate generates a mass scale, its existence would exclude the IRFP. While the non-observation of the spontaneous chiral symmetry breaking is very suggestive, it by no means proves that the IRFP exists at non-zero coupling, and one needs to measure the evolution of the coupling directly 1.

II. LATTICE FORMULATION

The lattice theory is defined with the action

\[ S = S_G + S_F; \tag{3} \]

where \( S_G \) is the standard Wilson plaquette action for SU(2) gauge fields

\[ S_G = L \sum_{x,j} \frac{1}{2} \text{Tr}[U_{xj}U_{x+\hat{j}}U_{x+\hat{j}}U_{x-j}]; \tag{4} \]

\( S_F \) is the Wilson fermion action in the adjoint representation of SU(2):

\[ S_F = \sum_{x,j} \sum_{\xi} \bar{f}(x) D_{\xi} f(x + j); \tag{5} \]

where

\[ M_{xy} = x y (1 + \gamma_5 \gamma_x) + (1 + \gamma_5 \gamma_x)^T; \tag{6} \]

It differs from the standard Wilson fermion action only by the replacement of the fermion field representation link matrix \( U(x) \) with the adjoint representation ones:

\[ V^{ab}(x) = 2 \text{Tr} \left( \frac{1}{2} U(a)(x) U(b) \gamma_5(x) \right); \tag{7} \]

where \( a = \frac{1}{2}, b = 1; 2; 3 \) are the generators of the fundamental representation. The lattice action is conventionally parametrized with two dimensionless parameters,

\[ L = \frac{4}{g_0^2}; \quad \frac{1}{8 + 2a m_q 0}; \tag{8} \]

where \( a \) is the lattice spacing, and \( g_0^2 \) and \( m_q 0 \) the bare gauge coupling and quark mass. Because the Wilson action explicitly breaks the chiral symmetry of the continuum quark action, quark masses are additively renormalized and the bare quark masses must be tuned to achieve the massless limit. In order to keep the methodology simple, we do not implement zero \( a \) in the present on the lattice.

In earlier studies \([13,23]\) it has been found that in this lattice theory there exists a critical coupling \( L_F \) so that when \( L < L_F \) the theory shows signs of spontaneous chiral symmetry breaking, but reaching the limit \( m_0 \to 0 \) is prevented by the appearance of a first-order transition where \( m_0 \) goes to negative values. However, when \( L > L_F \) the \( m_0 \to 0 \) limit can be reached without observing the spontaneous chiral symmetry breaking. This is the region where it is possible to nd conformal behaviour in the limit if massless fermions.

Because the Wilson fermion action breaks the continuum chiral symmetry, the quark mass is additively renormalized and we determine the quark mass through the PCAC relation

\[ 2m_0 = \left[ \langle 0 \mid H_{\text{IR}}(x) \rangle \right]_{L_x = L_y = L_z}; \tag{9} \]

where \( V_A \) and \( V_P \) are (non-irreducible) axial and pseudoscalar current correlators \([23]\):

\[ V_A(x) = a^6 \sum_{x,0} \sum_{y,0} \sum_{z,0} \sum_{l,0} U(x) u(y,0) \delta(y,0) \delta(z,0) \tag{10} \]

\[ V_P(x) = a^6 \sum_{x,0} \sum_{y,0} \sum_{z,0} \sum_{l,0} U(x) u(y,0) \delta(y,0) \delta(z,0) \tag{11} \]

Here \( d \) and \( u \) refer to two quark flavours, and at finite values \( m_0 = 0 \) and \( x_0 = L \) the gauge fields are zero to specify Schrodinger function boundary values described in detail below. For each lattice coupling \( L \) we tune so that \( m_0 \) vanishes. This determines the critical point \( c(L) \); from now on we assume that we always tune to the limit \( m_0 = 0 \).

The coupling is measured using the Schrodinger functional (SF) method \([33,34,35]\), i.e., introducing a background field using special boundary conditions and studying the response of the system to changes of the background field. The scale at which the coupling is measured is determined by the system size of the system here we consider lattices of volume \( V = L^4 = (N a)^4 \), and following \([33]\), the spatial gauge links on the \( x_0 = 0 \) and \( x_0 = L \) boundaries are zeroed to constant diagonal SU(2) matrices:

\[ u(0) = \exp(i \frac{3a = L}{2}); \tag{12} \]

\[ u(L) = \exp(i \frac{d(\frac{3a = L}{2})}; \tag{13} \]

where \( d \) is the third Pauli matrix. The spatial gauge field boundary conditions are periodic. During the simulation the fermion fields are set to vanish at boundaries \( x_0 = 0 \) and \( x_0 = L \), and are timelike periodic to spatial directions:

\[ (x + L, x, y, z) = \exp(i \frac{d(\frac{3a = L}{2})}; \tag{13} \]

At the classical level the gauge field boundary conditions generate a constant color diagonal chromoelectric field, and the derivative of the action with respect to is easily calculable:

\[ \frac{\delta S_{\text{ch}}}{\delta} = \frac{k}{g_0^2}; \tag{14} \]

1 A modification one can study the properties of the physical degrees of freedom in the limit of zero quark mass as outlined in \([24]\).
\begin{align*}
\kappa &= 24(L=a)^2 \sin \frac{2}{(L=a)^2};
\end{align*}

At quantum level the boundary conditions generate a background field. Using an effective action, we have:

\begin{align*}
\mathcal{Z} &= \mathcal{D}[U;i] e^{\theta};
\end{align*}

where, on a lattice of size $L^4 = (N \times a)^4$, the coupling constant is defined through

\begin{align*}
\frac{\theta}{\eta} = \frac{\theta S_\eta}{\eta} = \frac{k}{g^2(L)};
\end{align*}

III. RESULTS AND ANALYSIS

As stated in the previous section we will consider lattice couplings $L < L_c = 2$ and tune to the $m_0 = 0$ limit corresponding to a critical value $c(L)$. The values of $c(L)$ as well as the corresponding $m_0$, at each value of $L$, used in this study are shown in Table I. The $L$-values which we consider are all larger than the critical value $L_c = 2$; indeed, already at $L = 1.9$ it was impossible to reach $m_0 = 0$ in it.

The measured $g^2(L=a; L)$ are done on lattices with volumes $V = a^4 = 4^4 \times 20^4$, with the results shown in Fig. 1 and tabulated in Table II. We use a hybrid Monte Carlo (HMC) algorithm with trajectory length $L$; the table also shows the number of HMC trajectories for each point. The measured $m_0$ of the coupling is done at the end of each trajectory. The acceptance rate in the

HM C algorithm remains better than 84% for all cases. For comparison, we made a small statistics study of the coupling using two of our fundamental fermions. These results are shown in Fig. 2.

What can we conclude from these results? We remark that we can directly compare physical lattice sizes only at fixed $L$; different $L$ correspond to very different lattice spacings. In the continuum $L$ is the sole physical scale, and $g^2(L)$ must be monotonic or (equivalently), $L$ is a function of $g^2$ through dimensional transmutation. Thus, the non-monotonic behaviour of data seen at $L = 2.25$ and 2.2 is caused by finite lattice spacing.
Figure 1: Lattice measurements of $g^2(L; a; \beta)$ for 2:\(\beta\) values of fundamental representation fermions, to be contrasted with the adjoint representation case in Fig. 2. The value of $g^2$ at $L=2a$, $L=a=16$ is 5/3. Continuous lines show $g^2(L)$ integrated using 2-loop $\beta$-function, constrained to go through lattice points at $L=a=16$.

Figure 2: Small-statistic measurements of $g^2(L; a; \beta)$ for 2:\(\beta\) values of fundamental representation fermions, to be contrasted with the adjoint representation case in Fig. 2. The value of $g^2$ at $L=2a$, $L=a=16$ is 5/3. Continuous lines show $g^2(L)$ integrated using 2-loop $\beta$-function, constrained to go through lattice points at $L=a=16$.

Figure 3: Step scaling ($L_1; L_2; a; \beta$) for different pairs of volume sizes, see Eq. (18), plotted against $1/g^2(L_1; a; \beta)$. The scaling factor is 2, except for the pair with largest volume size. Also shown is the 2-loop perturbative result for corresponding ratios of volume sizes.

Increasing, and the larger $g^2$ is, the steeper the increase. For the adjoint representation the observed xed point $g^2 = 2\cdots 3$ is significantly below the two-loop result 7.9.

Further analysis is needed in order to estimate the full $\beta$-function. The standard method proceeds through the measurement of step scaling functions; using lattices of sizes $L$ and $sL$, where $s$ is a scale factor, we measure $g^2(L; a; \beta)$ and $g^2(sL; a; \beta)$, thus obtaining a discrete step of the evolution of $g^2(L)$. Now we can search for $0$ so that $g^2(L; a; \beta) = g^2(sL; a; \beta)$. Repeating these scaling and matching steps the evolution of $g^2$ over a very large range of scales can be covered. The continuum limit extrapolation is enabled by redoing the analysis on different original $L=a=16$. This method has been successfully used, e.g. to determine the running coupling in QCD [22].

In Fig. 3 we show the step scaling using the quantity

$$\left( L_1; L_2; a; \beta \right) = \frac{1}{g^2(L_2; a; \beta)} \frac{1}{g^2(L_1; a; \beta)}$$

We use scaling factor $s = L_2/L_1 = 2$, except for the largest volume $e L=a=20$, where we do not have $L=a=10$ data available and use $s = 5/3$. We also show the 2-loop scaling result computed from Eq. (18).

If finite lattice spacing effects were absent, all points with the same $s$ should fall on a universal curve. This is clearly not the case; the small volume data lies significantly below the large volume points. We do not attempt to extrapolate the data to infinite volume (continuum limit), because we do not trust the smallest volume data to be close enough to continuum behaviour. Nevertheless, ($L_1; L_2; a; \beta$) become negative at small $a = g^2$, indicating the existence of the infrared xed point.
The main reason for the difficulty of using the step scaling method is that the evolution of $g^2(L)$ is very slow, much slower than with fundamental fermions. The slow evolution is easily masked by lattice artifacts at small $L=a$, whereas the faster evolution in fundamental fermion theory is rather easily observable. Improved actions can be expected to help significantly here. The slow evolution also increases the number of required recursive steps in the step scaling method and hence statistical errors.

Due to the numerical problems with the step scaling function mentioned above, we will therefore also consider the following alternative method: we use the measured values of $g^2(L=a)$ on volumes $12^3(20)^2$, and treat $g^2$ as a function ansatz to the data. The ansatz includes the small $g^2$ perturbative part and it should have only a few tunable parameters. The aim is to nd an envelope of continuum functions which are consistent with the measured results. The underlying assumption is that the lattice artifacts are already sufficiently small at $L=a = 12$. This should be checked with new simulations with improved actions in the future.

The simplest ansatz is the perturbatively motivated one: 

$$(g) = b_0 g^3 + b_1 g^5 + b_2 g^7.$$ 

Here $b_0$ and $b_1$ are fixed by the perturbative ansatz Eq. (2), and $b_2$ is a parameter. This function is actually consistent with the data, but it is very likely too constrained giving unrealistically small error range. In order to have independent parameters for the value of the xed point coupling and the slope of the $g$-function at the xed point, we are led to the following ansatz:

$$g = b_0 g^3 + b_1 g^7 + (b_2 g^3 + b_3 g^5) g.$$ 

A gain $b_0$ and $b_3$ are xed by the perturbation theory and $g$ and are parameters which determine the xed point and the slope of the $g$-function around the xed point. The ansatz is naturally not of a perturbative form at small $g^2$, but this does not matter for our purposes: the $g$-term turns out to be negligible at small $g^2$, and the purpose of the ansatz is to approximate the true $g$-function in the vicinity of the xed point. In practice equivalent results are obtained using perturbatively motivated ansatzes $b_2 g^3 + b_3 g^5$; however, Eq. (19) offers more freedom for the slope at $g^2 = g^2$.

We perform the fit as follows: integrating $(g) = L \log(L) = dL$ and constraining $g^2(L)$ to the lattice measurements at $L=a = 12$ for each $L$ gives us the continuous lines shown in Fig. 4. The integrated $g^2(L=a)$ are compared with the lattice measurement at $L=a = 16$ and 20, giving us a 2$\sigma$ criterion for the fit. Good fits ($\chi^2/d.o.f. = 1$) are obtained when parameters vary from $(g^2) = (22; 6)$ to $(22; 15)$ in a narrow region. Thus, the parameters are strongly correlated. The slope of the $g^2$-function at the xed point is a universal quantity, but it is only weakly constrained:

$$\frac{dg}{dg^2} = 0.12 \pm 0.04.$$ 

We take $g^2 = 22$, $x = 7$ to be our benchmark value, which is motivated by the fact that $x = 7$ is the order of the NNLO perturbative $g$-function. These lines are shown in Fig. 1. However, we by now means imply that the xed value gives the perturbative result; it only quanti es all unknown contributions. If we take $x = 7$, $g^2$ can vary between 2.05 and 2.4.

The result of the fitting procedure is shown in Fig. 4, together with the error band formed by the variation of the parameters in the region where acceptable fits are obtained. While the error band is wide, the qualitative features agree with the corresponding step scaling functions calculated from the measurements; both methods indicate positive $g$ at large $g^2$. We also note that the two-loop perturbative $g$-function alone ts the measurements well at $L > 3$ ($g^2 < 2$).

Fig. 4 shows the three- and four-loop M S-scheme results [29]. Because of the di erent scheme, these are not directly comparable with the SF-scheme results obtained in our simulations [1]. For example, the value of $g^2$ is scheme dependent. However, it is interesting that also in the M S-scheme the xed point is at substantially smaller $g^2$. 

\textsuperscript{2} Strictly speaking the fit is not optimal due to the constraint at $L=a = 12$. Relaxing this constraint gives better $\chi^2$, at the cost of a more complicated fit procedure. However, because $L=a = 12$ has smaller errors than larger volumes the effect is small.
Thus, the evidence for the two-loop perturbative function alone gives us an acceptable fit, if we ignore the data at $L = 2.5$ ($g^2 > 2.7$). Indeed, in that case it is possible to a function which does not feature an IR fixed point. Thus, the result is that the two-loop perturbative function fails although the nonperturbative analysis in planes $g = g'$ is small. Since the perturbative determination of the fixed point is based on the competing effects from one- and two-loop order, it is reasonable to expect that higher loop orders can contribute with similar magnitude and one needs nonperturbative analysis. This is seen in the $M$-scheme results in Fig. [3]. Beyond two loops the value of $g^2$ is scheme dependent; our result is in $M$-scheme. Comparison of the nonperturbative result and the perturbative curves in Fig. [3] demonstrates that even if the actual value of the coupling at the fixed point is small, the nonperturbative eects can be large.

When we combine the results of the analysis here with the spectrum measurements of ref. [2], a consistent picture emerges. In the whole paramater range where simulations with massless fermions are possible the infrared behaviour is controlled by the conformally invariant fixed point $g^2$ and there is no chiral symmetry breaking. If $g^2 < g^*$, the theory is asymptotically free, otherwise not. The conformal invariance can be explicitly broken by e.g. adding a small fermion mass, which can lead to a "walking" type evolution.

As discussed above, for the lattice action used here it has been observed that it is not possible to take the limit $m_0 	o 0$ when $L < 2$. Thus, the $L = 2.05$ points in Fig. [3] are close to the smallest $L$ where the conformal behaviour can be studied. This limitation is a non-universal lattice artifact, and may differ for some other fermion discretisation. This motivates a study with fully $O(a)$ improved lattice fermions.

IV. CONCLUSIONS AND OUTLOOK

Let us now discuss the interpretation of these results. We note that the observed range for the critical coupling, $g^2 = 20$ (3.2 is significantly below the perturbative estimate $g^2 = 8$ from Eq. (2)). Similar behaviour has been observed in SU(3) gauge theory with 2-index symmetric fermions [14]. The obvious question is why the perturbative two-loop function fails although the nonperturbative analysis in planes $g = g'$ is small. Since the perturbative determination of the fixed point is based on the competing effects from one- and two-loop orders, it is reasonable to expect that higher loop orders can contribute with similar magnitude and one needs nonperturbative analysis. This is seen in the $M$-scheme results in Fig. [3]. Beyond two loops the value of $g^2$ is scheme dependent; our result is in $M$-scheme. Comparison of the nonperturbative result and the perturbative curves in Fig. [3] demonstrates that even if the actual value of the coupling at the fixed point is small, the nonperturbative effects can be large.

When we combine the results of the analysis here with the spectrum measurements of ref. [2], a consistent picture emerges. In the whole parameter range where simulations with massless fermions are possible the infrared behaviour is controlled by the conformally invariant fixed point $g^2$ and there is no chiral symmetry breaking. If $g^2 < g^*$, the theory is asymptotically free, otherwise not. The conformal invariance can be explicitly broken by e.g. adding a small fermion mass, which can lead to a "walking" type evolution.

As discussed above, for the lattice action used here it has been observed that it is not possible to take the limit $m_0 	o 0$ when $L < 2$. Thus, the $L = 2.05$ points in Fig. [3] are close to the smallest $L$ where the conformal behaviour can be studied. This limitation is a non-universal lattice artifact, and may differ for some other fermion discretisation. This motivates a study with fully $O(a)$ improved lattice fermions.
