(Dated: June 30, 2013)

A detailed non-linear analysis of the internal structure of spherical, charged black holes that are accreting scalar matter is performed in the framework of the Brans-Dicke theory of gravity. We choose the lowest value of the Brans-Dicke parameter that is compatible with observational constraints. Firstly, the homogenous approximation is used. It indicates that mass in action occurs and that the variations of the Brans-Dicke scalar inside the black hole, which could in principle be large in the absence of mass in action, become small when mass in action does occur. Then, a full non-linear numerical study of the black hole interior perturbed by a self-gravitating massless uncharged scalar field is performed. We use an algorithm with adaptive mesh refinement capabilities. In this way, the changes in the internal structure of the black hole caused by mass in action are determined, as well as the induced variations of the Brans-Dicke scalar, confirming, qualitatively, the indications given by the homogenous approximation.

I. INTRODUCTION

It has long been known that the internal structure of an eternal Reissner-Nordstrom or Kerr black hole must be drastically altered by accretion. Firstly, a Reissner-Nordstrom or Kerr black hole has an inner horizon covering a gravitationally repulsive singularity, which is qualitatively different from a Schwarzschild black hole: it is unreasonable that the accretion of an instantaneous amount of charged or spinning matter could lead to such a drastic change in the black hole interior. Secondly, there are arguments of both physical and mathematical nature \cite{1}, indicating that the Cauchy horizon (i.e. inner horizon) of the eternal charged or rotating hole is unstable against small (linear) perturbations. The natural question is then, what is the endpoint of the instability? Answering it should shed some light on the internal structure of realistic astrophysical Kerr black holes.

Studying general perturbations of a stationary axisymmetric spacetime is a hard problem in general relativity \cite{2}. Thus, the aforementioned questions can be initially considered in the context of perturbations of the Reissner-Nordstrom black hole, as a simple model for the more challenging realistic case of the Kerr black hole. This was the route followed by Poisson and Israel, in their seminal work where the phenomenon of mass in action was unveiled \cite{1,2}: if ingoing and outgoing streams are simultaneously present near the inner horizon, then relativistic counter-streaming between those streams leads to exponential growth of gauge-invariant measures such as the inner (\textit{\textsuperscript{II}} inner-Sharpe \cite{3}) mass, the center-of-mass energy density, or curvature scalar invariants. Since this effect is causally disconnected from any external observer, the mass of the black hole measured by an outside observer remains unchanged by the mass in action going on in the interior. But this in action phenomenon causes the spacetime curvature to grow to Planckian values on a space-like hypersurface in the neighbourhood of the Cauchy horizon.

A lot of effort has been put into understanding detailed aspects of the mass in action phenomenon, within general relativity. In their original work, Poisson and Israel gave analytical arguments to support that the exponential growth of the internal effective mass was sourced by the existence of both ingoing and outgoing \textit{uxes} (relativistic counter-streaming). According to these authors, the ingoing \textit{ux} is in principle blueshifted as it approaches the Cauchy horizon. But by itself this does not suffice to trigger mass in action; an outgoing \textit{ux} that induces a separation between the Cauchy and the inner apparent horizon is also necessary.

Various other numerical and analytical studies in the framework of general relativity have shown that mass in action develops naturally when a massless scalar \textit{eld} is accreted by a spherical charged black hole \cite{4,5,6,7,8,9}. Perturbations of the scalar \textit{eld} propagate at the speed of light, and outgoing \textit{uxes} are produced as a result of the scattering of the ingoing scalar \textit{eld} by the space-time curvature, leading again to counter streaming and to mass in action. Yet another example has been provided in \cite{10,11} by studying the self-similar accretion of charged baryons into spherical black holes, showing that mass in action occurs if an additional neutral matter component is present. In this case it is the relativistic counter-streaming between ingoing neutral matter and outgoing charged baryons that appears to be responsible for mass in action. The physics of the relativistic counter-streaming that drives mass in action inside black holes is further analysed in \cite{12}.

But it has not been explored, so far, if these dramatic
events taking place inside a black hole still occur in a more general theory of gravity. This is the programme we wish to start with the present paper.

To be concrete, we shall consider one of the simplest extensions of general relativity, the Brans-Dicke (BD) theory of gravity, a well-known example of a scalar-tensor theory in which the gravitational interaction is mediated by a scalar field, in addition to the metric. BD theory is parametrized by one additional parameter, ω, as compared to general relativity, which is obtained in the limit ω → 1. Hence, this theory passes all available experimental tests if ω is large enough. The most stringent limit was obtained from precision measurement of the timing of signals from the Cassini mission which constrained ω to be larger than 40000.

The key observation for the present study is quite simple. If BD theory is minimally coupled to the Maxwell field, such is the model that solves standard Reissner-Nordstrom black hole of Einstein-Maxwell theory, irrespective of the value of ω. Indeed, the variations of the BD scalar field are sourced by the trace of the matter energy-momentum tensor T^μν:

\[ T^\mu_\nu = \frac{8T}{3+2\omega} ; \]

which is zero for a classical electromagnetic field. Thus, the BD scalar can be taken as constant, and the theory reduces to Einstein-Maxwell with an extra (irrelevant) scalar field.

Matter perturbations with non-vanishing energy-momentum trace will, however, induce variations of the BD scalar. Since this scalar determines the gravitational coupling to matter, it in essence a back reaction of matter on the geometry. A priori, there are reasons to expect these variations to be large. The first reason is that equation (1) with negligible or no sources, specialized to a stationary spherically symmetric spacetime in spherical coordinates,

\[ ds^2 = g_{tt}(r)dt^2 + g_{rr}(r)dr^2 + r^2d\Omega^2 ; \]

yields, in a region where the metric coefficients have fast variations (this follows from below)

\[ \frac{d}{dr} / \frac{g_{rr}}{g_{tt}} ; \]

thus, near a horizon, in particular near the Cauchy horizon, one could expect large variations of if an (even tiny) source term or perturbation exists. The second reason is that mass in action could potentially lead to a large right hand side of (1). Thus, two natural (and related) questions follow: (a) does mass in action still occur? (b) are there significant variations of the BD scalar, and hence of the gravitational coupling to matter?

In this paper we shall answer the above two questions, by studying the space-time geometry and the dynamics of the matter fields in the interior of a black hole in the framework of BD gravity.

We shall see that, choosing the lowest value of ω compatible with observational constraints, mass in action occurs much in the same way as in general relativity, and no substantial variations of the Brans-Dicke scalar field are found. That varies little is actually a surprising conclusion, in view of the above arguments. As we shall argue, it is actually the mass in action phenomenon that, in our model, prevents larger variations from being produced.

This paper is organized as follows. We start by introducing our model in section II. In this section we discuss the equations of motion, assuming spherical symmetry, specify the initial conditions for a full numerical integration and discuss the numerical algorithm used. In section III we describe the homogeneous approximation, from which we extract both numerical and analytic information about the occurrence of mass in action and the variations of the Brans-Dicke scalar. In section IV we perform a full non-linear numerical evolution of the black hole interior perturbed by a self-gravitating massless scalar field, using both a compact and a non-compact perturbation. In section V we draw conclusions.

II. MODEL

A. Field equations with spherical symmetry

Consider the Brans-Dicke (BD) action:

\[ S = \int d^4x \sqrt{g} \left( \frac{R}{16} + \frac{\omega}{2} \right) + 16 L_M ; \]

where R is the Ricci scalar, is a real scalar field and L_M is the matter Lagrangian, which we will assume to be the sum of the usual Maxwell contribution, L_F, and the contribution of a self-gravitating real massless scalar field

\[ L_M = L_F + L_s = \frac{F^2}{16} \frac{1}{g^2} ; \]

where \( F^2 = F^\mu_\nu F_{\mu\nu} \) and F is the Maxwell tensor. Our signature choice is −+++. The energy-momentum tensor of the matter fields is given by

\[ T^\mu_\nu = F^\mu_\nu + \frac{\omega}{2} g^\mu_\nu \]

\[ + \frac{\omega}{2} \left( \frac{\omega}{16} \right) \]

where

\[ F^\mu_\nu = \frac{1}{4} \left( \frac{1}{4} F \right) \]

\[ + \frac{1}{2} \left( \frac{1}{2} g \right) \]

The energy-momentum of the BD field is

\[ T^\mu_\nu = \frac{1}{4} \left( \frac{1}{4} \right) \left( \frac{1}{2} g \right) \]

\[ + \frac{1}{2} \left( \frac{1}{2} g \right) \]

Thus

\[ T^\mu_\nu = \frac{1}{4} \left( \frac{1}{4} \right) \left( \frac{1}{2} g \right) \]

\[ + \frac{1}{2} \left( \frac{1}{2} g \right) \]
The equations of motion derived from (9) with (6) are the gravitational equations

\[ G = \frac{8}{r^4} (T^T + T) ; \]  

(10)
equation (11) for the BD field, with \( T^M T \), and the matter equations

\[ \gamma = 0 ; \quad d \Omega^F = 0 ; \]  

(11)
where \( \gamma \) denotes Hodge dual.

To solve the coupled system (1), (10) and (11), we take a spherically symmetric ansatz written in double-null coordinates. Thus

\[ ds^2 = 2 \frac{2}{\gamma} (u^r)^2 du dv + r^2 (u; v) d\gamma^2 ; \]  

(12)

\[ = (u; v) ; \quad F = F \left( u; v \right) du \wedge dv ; \quad \gamma = \gamma(u; v) ; \]  

(13)
where \( u \) and \( v \) are taken to be ingoing and outgoing respectively. Under a gauge transformation of the form \( u \) function of \( u \) and \( v \) function of \( v \), the coordinates \( u \) and \( v \) still preserve their null character; this will be of use later.

The Maxwell equations (11) are simply solved to yield

\[ F_{uv} \gamma^2 e^{2\gamma} = \text{constant} = q ; \]  

(14)
where

\[ q = \frac{1}{8} \quad F ; \]  

(15)
is the electric charge. The electric field is therefore purely radial, as expected from spherical symmetry. The scalar field equation (11) gives

\[ \gamma_{uv} = \frac{1}{r} \left( r^p_{uv} - r_{u}^{p} - r_{v}^{p} - p \right) ; \]  

(16)
The \( uu, vv, uv \) and \( vu \) components of the Einstein equations (10), which are the only distinct non-trivial ones, give rise to the following equations (the left hand sides these equations are components of the Einstein tensor \( G \)):

\[ \frac{4r_{u}^{p} - 2r_{u}}{r} = 2\left( \gamma_{u}^p + \gamma_{u} - 2 \gamma_{u}^p - p \right) + \gamma_{uu} \frac{2}{r} \]  

(17)

\[ \frac{4r_{v}^{p} - 2r_{v}}{r} = 2\left( \gamma_{v}^p + \gamma_{v} - 2 \gamma_{v}^p - p \right) + \gamma_{vv} \frac{2}{r} \]  

(18)

\[ \frac{e^{2} + 2r_{u}r_{v} + 2r_{u}r_{v}}{r^2} = \frac{q^2 e^{2}}{r^4} - \gamma_{uv} \frac{2(r_{u} r_{v} + r_{v} r_{u})}{r} ; \]  

(19)
Equations (17)-(18) are two constraint equations, whereas equations (19)-(20) are evolution equations. In the former equations, the contribution from the energy-momentum of the scalar field is

\[ T_{uv} = \left( \frac{\gamma_{u}^p}{4} \right) ; \quad T_{vv} = \left( \frac{\gamma_{v}^p}{4} \right) ; \]  

(21)
respectively, which represent, physically, the \( uu \) of the scalar field through surfaces of constant \( v \) and \( u \), i.e. outgoing and in going. We shall impose that, initially, only in going \( uu \) exists, equation (20). However, out going \( uu \) is inevitably produced by scattering of the spacetime geometry.

Finally, the wave equation (9) for the Brans-Dicke scalar field is

\[ \gamma_{uv} = \frac{1}{r} \left( r_{u} r_{v} - r_{u} r_{v} - \gamma_{uv} \right) \frac{2}{3} \frac{2}{2} ; \]  

(22)

B. Initial conditions

Without loss of generality, we take the initial unperturbed RN black hole to have mass

\[ m_{0} = 1 ; \]  

(23)
which is simply a choice of units. Observational evidence [20, 21, 22, 23] suggests that astronomical black holes have large spins in several cases. We therefore take the unperturbed RN black hole to have a charge near the extremal value of unity,

\[ q = 0.95 ; \]  

(24)
The corresponding radii \( r \) and \( r \) of the unperturbed inner and outer horizons are

\[ r \quad 0.99 ; \quad r \quad 1.31 ; \]  

(25)
Note that the mass of the black hole will change with accretion, but not its charge.

The numerical integration is performed in double-null coordinates \( u, v \) over an integration box \( u_{0} = 0 \quad u < 30, \quad v_{0} = 5 \quad v < 20 \). Initial conditions are prescribed along the two null geodesics \( u = u_{0} \) and \( v = v_{0} \). Prior to \( v = v_{0} \), the geometry is Reissner-Nordstrom. We consider two cases, one in which the black hole is fed with a non-com pact in \( uu \) of scalar field that extends over a finite time, and another in which the black hole is fed with a non-com pact in \( uu \) that starts at a certain time and then continues indefinitely. Fig. illustrates the initial conditions for the case of the non-com pact in \( uu \); the case of the non-com pact in \( uu \) is similar.
Fig. 1: Initial conditions in the num erical integration box, de ned by \( u_0 = 0 \) \( u < 30, v_0 = 5 \) \( v < 20 \), for the case where the black hole is fed by a com pact in u x of scalar eld \( \phi \). The unperturbed black hole has mass and charge \( m_0 = 1, q = 0.95 \). The in u x along the null se gm ent \( u = u_0 \) starts at \( v_0 = 5 \), has an plume A = 0.05 or A = 0.1, and endures for \( v = 1 \). The in u x, depicted by a curve, is non-zero only for \( v_0 < v < v_0 + v \). The scale in the \( u \) and \( v \) axes is 1/16 en t to make closer contact with the Carter-Penrose diagram s hown in Figs. 3 and 5.

The gauge freedom associated with the transforma tions \( u \mapsto f(u) \) and \( v \mapsto f(v) \) can be used to make \( r \) linear in \( u \) and \( v \) on the initial null se gm ent, so that

\[
r(u_0; v) = 0; \quad r(u; v_0) = v_0 + u r_{u_0}(u_0; v_0):
\]

Defining \( r_0 \), \( r(u; v_0) \), equations (26) show that

\[
r_0 = \frac{v_0}{v}:
\]

We choose

\[
r_0 = 5;
\]

which is well outside the outer horizon. This ensures that the null se gm ent \( u = u_0 \) along which the initial in u x (39) or (41) of scalar eld \( \phi \) is speci ed everywhere welloutside the horizon. The M ienser-Sharpe \[ 6 \] m ass function, the total e ctive m ass inside a sphere of radius \( r(u; v) \), is equal to

\[
m(u; v) = \frac{r}{2} \left( 1 + \frac{q^2}{r^2} \right) q^1;
\]

\[
= \frac{r}{2} \left( 1 + \frac{q^2}{r^2} + \frac{4 r_{u_0} r_{u_0}}{2e^c} \right):
\]

Equation (29) im plies that \( r_{u_0}(u_0; v_0) \) in equation (26) is related to the initial m ass \( m_0 \) and charge \( q \) of the black hole by

\[
r_{u_0}(u_0; v_0) = \frac{1}{4} \frac{2}{r_0} m_0 \frac{q^2}{2e_0} 1:
\]

For the Brans-Dicke eld, which is observationally constrained to vary little outside the black hole, we choose initial conditions

\[
(u_0; v) = 1 = (u; v_0):
\]

This im plies

\[
\rho (u; v) = \rho (u_0; v_0) = 0; \quad \rho (u_0; v) = 0:
\]

The constraint equations (10) and (11) then become

\[
\rho (u; v_0) = \frac{r_0 + u r_{u_0}(u_0; v_0)}{2r_{u_0}(u_0; v_0)} \left( \rho (u_0; v)^2 \right); \quad \rho (u_0; v) = \frac{v}{2} \left( \rho (u_0; v)^2 \right):
\]

We assume that there is no out u x along the initial null se gm ent \( v = v_0 \)

\[
\rho (u; v_0) = 0:
\]

Equation (31) im plies that the scalar eld \( \phi \) is constant along the null se gm ent \( v = v_0 \), and, since \( \phi \) is de ned only up to an overall constant, without loss of generality we take this constant to be zero.

\[
\rho (u; v_0) = 0:
\]

Equations (30) and (31) together im plies that \( \rho (u; v_0) = 0 \), which is constant along the null se gm ent \( v = v_0 \). The constant can be chosen arbitrarily, since the choice (26) still leaves a gauge freedom in the overall scaling of \( u \), and we choose

\[
(u; v_0) = (u_0; v_0) = \ln(2) = 0:
\]

equivalent to choosing \( \rho (u_0; v_0) = 1 \) in the line element (12).

The last initial condition to be speci ed is the in u x \( \rho (u; v) \) of the scalar eld along the null se gm ent \( u = u_0 \). We consider two cases, one consisting of a com pact pulse of in u x, the other a non-com pact in u x. The com pact pulse represents an accretion event that takes place over a nite time, while the non-com pact in u x represents accretion that continues into the inde nite future.

For the com pact pulse, we choose the in u x of scalar eld along the initial null se gm ent \( u = u_0 \) to be

\[
\rho (u; v) = \frac{A}{v} \left( 1 + \frac{v}{v_0} \left( 1 + \frac{v}{v_0} \right) \right); \quad v_0 = 1:
\]

vanishing outside the interval \( v_0 \) to \( v_0 + v \). We choose an interval

\[
v = 1:
\]

The pulse has an plume A. For \( A = 0 \), there is no pulse, and num erical integration yields the unperturbed RN black hole (see subsection 11D). The behavior of the pulse along the null se gm ent \( u = u_0 \) follows from integrating equation (32).

For the non-com pact in u x, we choose the in u x of scalar eld along the initial null se gm ent \( u = u_0 \) to be

\[
\rho (u; v) = \frac{A}{v}:
\]
FIG. 2: The radial coordinate \( r \) as a function of \( u \) and \( v \) close to the inner ingoing apparent horizon (top) and outer ingoing apparent horizon (bottom), for the unperturbed RN black hole with \( m = 1 \) and \( q = 0.95 \). Horizons are at \( r = 0.6876 \) and \( r = 1.31 \), in agreement with analytical expectation. Contours are plotted only for \( r \) in the range of the color bar, \( r \in [0.6876,0.6879] \) in the top panel, \( r \in [1.2,1.4] \) in the bottom panel.

C. Numerical algorithm

We integrate the eik equations using a second order algorithm similar to that used by other authors (see for example \[13\] and references therein). The four evolution equations can be written as

\[
Y_{P^j}^{jk} = F_j^{j}(Y_{P^k}^{i,k} Y_{P^k}^{i,k}) ; k = 1,4 ; \quad (42)
\]

with \( Y_{P^j}^{j} = r_P \),  for \( j = 1 \) to \( 4 \) respectively. The numerical code determines the values of the variables \( Y_{P^j}^{j} \) in the \((u,v)\) numerical grid solving, for each \( v = v_0 + n_v \), equation \ref{42} for \( u = u_0 + n_u \) (starting at \( n_u = 1 \) until the last point \((u_{\text{F}},v_{\text{F}})\) is finally reached. We perform standard numerical tests by running various simulations with different resolutions \((u,v)\), verifying that the code is indeed accurate to second order in \( u \) and \( v \).

Although in double-null coordinates all the eikls are regular, there is a numerical difficulty across the event horizon of the black hole, since \( r_{\text{H}} \) diverges along the event horizon (see Fig. 2 (bottom)). In order to maintain numerical precision, we used an algorithm with adaptive mesh refinement (AMR) in one direction. Given that strong gradients appear mainly in the \( u \)-direction, the AMR algorithm modifies the increment \( u \) in such a way that \( r < 10^{-4} \). This unidirectional approach is possible since Courant-like stability constraints on the step size are avoided by the use of null coordinates.

D. Unperturbed black hole

Fundamental to the interior structure of a black hole is the location of its apparent horizons. Fig. 2 reveals the location of these horizons in the \((u,v)\) plane for the unperturbed case. Fig. 3 shows the coordinate \( r \) as a function of \( u \) and \( v \) for the unperturbed RN black hole (without accretion, \( A = 0 \)). Recall that an apparent horizon may be loosely defined as the boundary between the region where outwardly directed light rays (i.e., with \( u = \) constant and increasing \( v \) in null coordinates) move outwards (i.e., to larger \( r \)) and the region where outwardly
directed light rays move inwards. Apparent horizons are defined locally, and their locus is not, in general, a covariant statement; it depends on the chosen time foliation of the spacetime. An illustrative example is that the Schwarzschild solution may be foliated such that it has no apparent horizon [24], despite the presence of an event horizon, which is a covariant (and global) statement.

In terms of the chart [22], apparent horizons are the set of points \((u, \nu)\) such that

\[
\frac{\partial r}{\partial v}(u, \nu) = 0 \quad (43)
\]

This equation defines a curve in the \(uv\) plane. Fig. 2 shows that the apparent horizons lie along \(u = \text{constant}\), and that \(r(u, \nu)\) \(\rightarrow 0\) to good accuracy, meaning that the radial of the apparent horizons coincide with the expected radius of the outer and inner event horizons, equations [23]. This is a good test of the code. As a further test we were able to reproduce the results reported by [13].

The content of Fig. 2 can also be understood in the context of the Carter-Penrose diagram of an eternal RN black hole. Fig. 3 shows the Carter-Penrose diagram, outlining the regions covered by Fig. 2. The diagram reveals the same pattern of lines of constant \(r\) as Fig. 2.

III. HOMOGENEOUS APPROXIMATION

Results will be presented in section IV, but rst it is useful to gain insight by applying the homogeneous approximation [3,25,26].

If the black hole is accreting at a low rate, it is reasonable to expect that the geometry, at least outside the region where mass addition is occurring, would approximate that of a stationary black hole, a Reissner-Nordstrom black hole. A stationary black hole has the property of time translation invariance

\[
\frac{\partial }{\partial t} = 0 \quad (44)
\]

Inside the horizon, the time coordinate is spacelike, and [3,25,26] has called the proposition that equation [44] holds inside the horizon the homogeneous approximation. [16] point out that the homogeneous approximation [44] fails in the information zone even in the limit of infinitely small accretion rates. Rather, the homogeneous approximation [44] is equivalent to the assumption of symmetrically equal ingoing and outgoing \(u\). The initial conditions prescribed in subsection IIB are asymmetric between ingoing and outgoing, so the homogeneous approximation [44] is not expected to hold.

However, the homogeneous approximation [44] simplifies them at least because it means that all quantities are functions only of the radial coordinate \(r\). Although the assumption of symmetrically equal ingoing and outgoing \(u\) is not realistic, nevertheless the behaviour in this case may provide insight into the more realistic case of unequal ingoing and outgoing \(u\).

A. Field equations

The spherical symmetric, homogeneous line-element is given by eq. (2). The \(tt\) and \(rr\) components of the Einstein equations [10] are then

\[
g_{tt} \frac{g_{rr}^2 \rho^2}{T'^2} = \frac{2}{3} \frac{M}{T_t^c} + \frac{2}{3} \frac{M}{T_r^c} \quad (45)
\]

\[
g_{tt} \frac{g_{rr} \rho^2 + \rho^2}{T'^2} = \frac{2}{3} \frac{M}{T_t^r} + \frac{2}{3} \frac{M}{T_r^r} \quad (46)
\]

where the prime denotes a derivative with respect to \(r\). Energy-momentum in angular directions follow from the energy-momentum in \(t\) and \(r\) directions, together with the equations of covariant conservation of energy-momentum. The non-vanishing components of \(T\), \(T^t\) and \(T^r\) are, in \(ft\); \(g\) coordinates,

\[
T^t = \frac{(r^0)^2}{8} \frac{T^t}{g_{tt}} \quad (47)
\]

\[
T^r = \frac{g^2 - r^2}{8} \frac{T^r}{g_{tt}} \quad (48)
\]

\[
T_t^c = \frac{1}{8} \frac{g_{tt}^0 - g_{rr}^0}{g_{tt}} \quad (49)
\]

\[
T_r^c = \frac{1}{16} g_{tt}^0 \quad (50)
\]

whence

\[
M T = \frac{(r^0)^2}{4 g_{tt}} \quad (51)
\]

In the above we have taken into account that the black hole charge will give rise to an electrostatic field which is purely radial and consequently the only non-zero components of the electromagnetic tensor, \(F\) are \(F_{tr} = F_{rt}\). It is then straightforward to show from Maxwell's equations that

\[
F_{tr} = \frac{q^2}{r^2} \quad (52)
\]

The wave equation [11] for the scalar field \(\phi\) can be written as a second order equation

\[
\frac{\partial ^2 \phi}{\partial r^2} = \frac{1}{g_{tt}} \frac{1}{g_{tt}} \quad (53)
\]

while the wave equation [11] for the Brans-Dicke field becomes

\[
\frac{\partial ^2 \phi}{\partial r^2} + \frac{2}{g_{tt}} \frac{\partial \phi}{\partial r} + \frac{4}{g_{tt} g_{rt}} = \frac{8 \phi}{3} \quad (54)
\]

From equations [51] and [53] (54), one reads that the source term for variations is proportional to

\[
\frac{1}{g_{tt} g_{rt}} \quad (55)
\]

Thus, we conclude that the source term for variations, depends strongly on the ratio \(g_{rt}^2 = g_{tt}\). We shall return to this point in section IIIIB.
B. Generalized scalar field

A massless scalar field has sound speed equal to the speed of light. As originally envisaged by [4], mass inflation is expected to result from relativistic counter-streaming between an in flux and out flux of scalar field. We now introduce a generalized scalar field, which allows us to vary the speed of sound and hence have modes with and without mass inflation. Our goal is to see the consequences, within the homogeneous approximation, for the variations of the Brans-Dicke scalar.

Consider a generalized scalar field whose action is

$$ S = \int \mathcal{L}(\phi; X) \sqrt{-g} \, \text{d}^4 x $$

where $X = 2$. It follows that the energy-momentum tensor of the generalized scalar field is that of a perfect fluid [27]

$$ T = (\phi + p) U + p $$

with 4-velocity

$$ U = \frac{1}{X} $$

and proper energy density and pressure $= 2X p$, $p$ and $p = L$. If $\phi$, is timelike then the scalar field is from ally equivalent to a perfect fluid. Generally, $\phi$ need not be timelike, but it is timelike in the homogeneous case (cf. subsection III C).

In the general case $p(\phi; X)$, the pressure cannot be expressed only in terms of $\phi$, since for a fixed $X$ and $p$, a given event will always be possible to have different $p_X$ by changing the value of $\phi$ at that event. On the other hand, if $p(X)$ then both $p$ will be functions of $X$ alone, and consequently the relation between $p$ and $w$ is established once $X$ is fixed. If $p / X (1 + w) = -2w$ with $w = \text{constant}$, then

$$ p = w $$

The corresponding sound speed $c_s$ is

$$ c_s = \frac{dp}{d\phi} = \frac{p}{w} $$

For example, the Lagrangian density $L / X$ yields the usual massless scalar field model with equation of state $p = \phi$. The model discussed in the previous subsection III A. As another example, $L / X^2$ describes an ultra-relativistic fluid with equation of state $p = -3$. As another example, $L / X^n$ as $n \to 1$ describes a pressureless fluid (dust).

C. Homogeneous generalized scalar field

The homogeneous approximation implies that $\phi$ is a function of $t$ only. The only non-vanishing component of the 4-velocity $U / U / \phi$, equation (53), is therefore $U^\mu$. Since $g_{\mu\nu} < 0$ inside the horizon, $U^\mu$ is

$$ U^\mu = \frac{1}{U^\nu} = \frac{p}{g^{\mu\nu}} $$

where the sign is for $\mu > 0$ and + for $\mu < 0$. The 4-velocity $U$ is timelike, and therefore the behavior of the generalized scalar field is identical to that of a perfect fluid. The energy-momentum tensor $T_{\mu\nu}$ of the generalized scalar field is

$$ T_{\mu\nu} = T = T = p = w = \eta T_c $$

and the trace of the matter energy-momentum tensor becomes

$$ T = 3w \eta $$

The proper energy density in terms of the metric coefficients follows from energy-momentum conservation, $T_{\mu\nu} = 0$, which implies

$$ \eta = T_{\mu\nu} = \frac{g_{\mu\nu}}{g_{\mu\nu}} \left( 1 + w \right)^2 $$

where $\eta$, $g_{\mu\nu}$ and $r_0$ are all integration constants; $\eta$ is the density at the surface $r = r_0$, where $g_{\mu\nu}$ is $g_{\mu\nu}$.

D. Initial conditions

Equations (63) and (64) denote the right hand side of the BD scalar equation of motion, and will be used in subsection III E. In solving the latter equation, we shall work in the limit where $\eta$ is small, and impose initial conditions inside the unperturbed outer horizon, since the homogeneous approximation, which requires symmetrically equal in $u$ and out $u$, fails outside the outer horizon. Moreover, we take the initial conditions in equation (64) to be

$$ r_1 = 0.95 r_0 ; \quad g_{\mu\nu} = 1 \quad \frac{2m}{r_1} + \frac{q^2}{r_1} $$

E. Results for the homogeneous approximation

We now present results for the homogeneous approximation applied to a generalized scalar field inside a spherical charged black hole in Brans-Dicke theory. We consider two cases, one with $w = 0$, the other with $w = 1$.

In the case with $w = 0$, mass in action does not occur and large variations of the Brans-Dicke scalar are present. By contrast, in the $w = 1$ case, mass in action occurs and variations are small. We will argue that it is actually mass in action that prevents large variations in the $w = 1$ case.

With the homogenous approximation, the task is to obtain the behavior of the metric coefficients in (2), i.e.
This corresponds to the standard case of a massless scalar field, the same as considered in section III, and can therefore be used to anticipate the results of section IV A. The behaviour is quite different from the \( \omega = 0 \) case. Fig. 3 (top) shows that both \( g_{rr} \) and \( g_{tt} \) decrease sharply (and proportionally) around \( r = 0.69 \). This indicates the presence of mass in action. A counter-intuitive fact shown in this plot is that for small values of the initial energy density, mass in action is more abrupt.

Fig. 3 (bottom) shows the behaviour of the Brans-Dicke scalar. At around \( r = 0.69 \), where mass in action starts, there is a clear jump in the variation of \( \Phi \), which is followed by a gentle decrease in the smaller radius. This indicates that the variations of \( \Phi \) are small in the mass in action region.

Having described the behaviour obtained from numerical integration we now try to understand it analytically. The case of \( \omega = 1 \), where mass in action occurs, indicates that the variations of are small (less than one percent); thus 1. It follows that \( j T \ j \ n \ T \ j \) and consequently \( T \) may be neglected in comparison to \( N \ T \).
Thus, $e^{-\frac{j}{y}}$ and $e^{-\frac{j}{y}}$ may be approximated by $e^{-\frac{j}{y}}$ and $e^{-\frac{j}{y}}$. In this approximation, the problem reduces to that of general relativity coupled to matter and a scalar field, without back-reaction from the Brans-Dicke scalar. Moreover, Fig. 6 shows that the variations of $g_{rr}$ and $g_{tt}$ are quite fast in the mass in action region. Thus, eqs. (45) and (46) may be approximated by

$$\frac{g_{rr}}{g_{tt}} = 8 \frac{T_{r}^{r}}{T_{t}^{t}} = 8 \frac{w^{4}}{r^{4}} T_{r}^{r};$$

(66)

$$\frac{g_{rr}}{g_{tt}} = 8 \frac{w^{4}}{r^{4}} T_{r}^{r};$$

(67)

These two equations imply that

$$\frac{g_{rr}}{g_{rr}} \approx \frac{g_{tt}}{g_{tt}} = \frac{g_{rr}}{g_{tt}};$$

(68)

Fig. 6 shows the ratio $g_{rr}/g_{tt}$ for the scenario with $w = 0$, where mass in action does not occur, and the one with $w = 1$, where it does. For the latter, the ratio is approximately constant in the mass in action region, in accordance with (68), even though each metric component individually varies rapidly, as shown in Fig. 5.

Equation (68), for $w = 1$, indicates that mass in action occurs. It follows from (64), (65) and (66) that

$$\frac{g_{rr}}{g_{tt}} \approx \frac{1}{r^{4}};$$

(69)

in the mass in action region. Then

$$g_{rr} / \exp \left( -\frac{w}{r} \right);$$

(70)

where $r$ scales roughly with $\frac{1}{p}$. Thus, the larger $r$, the larger the scale $r$ for variations of $g_{rr}$. This agrees with the behaviour observed in Fig. 5 (top): mass in action is more abrupt for smaller $r$.

Similarly, with this approximation scheme, we can obtain some analytical information for the variation of the Brans-Dicke scalar $\chi$ with $r$, using eq. (54). This equation may be written as

$$\frac{\rho}{\rho_{0}} + \frac{w}{2} \ln \left( \frac{\rho}{\rho_{0}} \right) = \frac{q}{r} = \frac{g_{rr}}{g_{tt}};$$

(71)

where $f(r)$ is some function of $r$, whose form is unimportant for this argument. If mass in action does not occur, as in the $w = 0$ case, both the metric fields and the source term diverge, from the behaviours of the metric scalar fields shown in Fig. 5. This produces a divergent behaviour of $\chi$, as seen in Fig. 5. If mass in action occurs, as in the $w = 1$ case, then equation (68) allows equation (71) to be written

$$\frac{\rho}{\rho_{0}} + \frac{w}{2} \ln \left( \frac{\rho}{\rho_{0}} \right) = \frac{g_{rr}}{g_{tt}} = C \left( \frac{g_{tt}}{g_{tt}} \right)^{-2} f(r);$$

(72)

where $C$ is a constant. Hence $w = 1$ is a special case where the metric fields and the source term are bounded as $g_{tt} \to 0$, and therefore the variations remain small in the mass in action region. This is consistent with the behaviour observed in Fig. 5 (bottom). Thus, one concludes that, for $w = 1$, it is the existence of mass in action that prevents large variations in the region around $r \approx 0.69$.

To sum up, the homogeneous approximation indicates that for $w = 1$, mass in action should occur and that the induced variations of the Brans-Dicke scalar (and therefore of the coupling constant) within the mass in action region are small. In the next section, we consider these indications by a full non-linear numerical evolution of the model of section 7.

IV. RESULTS

In this section we present results for a massless scalar field coupling to a spherical charge black hole in Brans-Dicke theory. We consider two cases, addressed in turn in subsections 4A and 4B, one in which the initial value of scalar field is turned on for only a finite time, equation (59), and another in which the initial inux starts at some future time and then persists into the infinite future, equation (71).

The equations to be solved are the four equations given by (59) and (19)–(22), which constitute a complete set of equations. The remaining Einstein equations, eq. (17) and (18), are automatically satisfied by covariant conservation of energy-momentum and can be used to check the accuracy of the numerical integration.

A. Full non-linear numerical evolution of a compact inux

In this subsection, the black hole is fed with a compact pulse of massless scalar field, equation (59).
Fig. 7: The radial coordinate $r$ as a function of the null coordinates $u$ and $v$ close to the inner apparent horizon when a single compact pulse with amplitude $A = 0.05$ (top) or $A = 0.1$ (bottom) and during $v = 1$ is fed on to an initially unperturbed RN black hole with $m = 1$ and $q = 0.95$. The radius $r$ is no longer a monotonic function of $u$ as in the unperturbed case (Fig. 2 (top)). The locus of the inner apparent horizon is a curve that interpolates between the maxima of $r$ at $v = 0$ of the $r = \text{constant}$ curves. For the pulse with larger amplitude, the inner apparent horizon changes more abruptly with $v$.

Fig. 8: This plot shows a detail of the radius $r$ in the vicinity of the outer horizon for the pulse with amplitude $A = 0.05$ (top) or $A = 0.1$ (bottom). The behaviour is similar to the case without accretion $A = 0$ (Fig. 2 (bottom)), which can be attributed to the fact that the accreted mass is small. The value of $u$ at large $v$ (in the future) differs noticeably from the zero accretion case.

$v$ increase), the $r$ coordinate of the inner apparent horizon decreases. This is to be expected. Indeed, the radii of the outer and inner horizons of a RN black hole vary with mass as

$$\frac{\partial r}{\partial m} = 1 - \frac{m}{q}.$$  \hspace{1cm} (73)

Consequently, increasing the mass of a Reissner-Nordstrom black hole with a fixed $q$ leads to a larger $r$, and a smaller $\partial r$. Of course, the geometry of an accreting black hole is not the same as the RN solution, but the observed decrease in the radius of the inner apparent horizon is consistent with equation (73).

By the same token, accretion is expected to cause the outer apparent horizon to become slightly larger compared to the unperturbed RN solution. This expectation is confirmed in Fig. 8, which shows a detail around the outer apparent horizon for the same simulations as Fig. 7. Fig. 8 shows two relevant features. Firstly, whereas at early times the plot is quite similar to that of the unperturbed case (Fig. 2 (bottom)), at late times there is a
FIG. 9: Heuristic Carter-Penrose diagram for the perturbed RN black hole. The initial perturbation is the curve depicted at the beginning of the integration box. The diagram is drawn to include the features observed in Fig. 7 and 8, namely that \( u_a \) increases/decreases with \( v_a \) for the inner apparent horizon (IAH) /outer apparent horizon (OAH). One expects the curvature to blow up at the Cauchy horizon (CH), and to become Planckian on a spacelike surface before the CH.

The slight but clear decrease in the \( u_a \) coordinate of the outer apparent horizon (clearly seen in Fig. II (bottom), but already noticeable in Fig. VI (top)). Secondly, \( r(u_a,\nu_a) \) is at late \( v \) time slightly, but again clearly, larger than the unperturbed value 131, as expected. The behaviour just described can be summarised in the heuristic Carter Penrose diagram of Fig. 9.

Fig. 10 shows \( \log_{10}(m) \) as a function of \( u \) and \( v \), exhibiting the mass in action profile close to the Cauchy horizon of the black hole. These figures show an exponential increase of the mass function as \( v \) increases. The increase is consistent with the theorems of [28,29], which show that, for a compact pulse as here, the mass tends to infinity and a mathematical singularity is attained at the Cauchy horizon, where \( v = 1 \). The expectation of a curvature singularity is supported by Fig. 11, which shows the scalar curvature of the spacetime:

$$ R = \frac{2}{r^2} + 2e \partial_r \partial_v r + r^2 \partial_v \partial_v r + 2r \partial_v \partial_v r $$

(74)

The same term \( e \partial_r \partial_v r \) that appears in (29) and is responsible for the mass in action phenomenon also appears in the Ricci scalar. Thus, not surprisingly, there is...
a strong growth of the curvature that accompanies the growth of mass, which is manifest in Fig. 11.

Although one expects that the curvature will diverge only on the Cauchy horizon (at $v = +1$), which is a null surface, it is important to remark that the curvature should reach Planckian values at finite values of $v$, on a spacelike surface. Beyond this point one expects quantum gravity corrections to become dominant effects, and therefore one cannot trust the geometry given by any classical theory of gravity.

Let us remark that the Cauchy horizon of the eternal RN black hole is composed of two lightlike sheets, as can be seen in Fig. 3, one corresponding to $v = +1$ and the other to $u = constant$ in our coordinates. The initial conditions in posed create an asymmetry between these two branches of the Cauchy horizon. These conditions are appropriate to see in one branch the mass in action phenomenon and in the other branch the evolution of the inner horizon under accretion. Thus, an outgoing ($u = constant$) observer sees mass in action (as $v$ increases, cf. Fig. 14), but an ingoing ($v = constant$) observer sees approximately constant mass, for large $u$.

Finally, Fig. 12 shows $1$ as a function of $u$ and $v$. It shows that the process of mass in action does not seem to drive rapid variations of the Brans-Dicke scalar. The largest variations are associated with the initial collapse of the scalar $\phi$ pulse onto the black hole. These fluctuations are transient, slowly fading away after the initial collapse of a self-gravitating massless scalar $\phi$ pulse. The amplitude of the fluctuations appears to increase again, slowly, towards the Cauchy horizon. But this growth tends to stop and to become a function of $r$ only, cf. Fig. 11 (top). This is consistent with the homogeneous approximation.

The model of the previous subsection, in which the black hole is fed with a compact pulse of scalar $\phi$ over only a finite time, is not realistic. The model is equivalent to assuming that the black hole remains isolated forever after accreting the pulse of scalar $\phi$. Real black holes are however never completely isolated, and they will continue to accrete at some rate or other until something completely different happens, like the black hole Hawking evaporating, or the Universe coming to an end in a big crunch.

In this subsection, the black hole is fed with an in $ux$ of massless scalar $\phi$ that starts at some time but then...
The results of the simulation for the structure of the inner and outer horizon are qualitatively similar to those of the compact pulse. The initial conditions were chosen so as to have a similar black hole mass variation, of the order of 1%, during the time spanned by the simulation, for both the compact and non-compact in ux. In the latter case, accretion would continue to increase the black hole's mass.

Figs. 13 to 15 show the mass function \( \log_{10} m \), the Ricci scalar \( \log_{10} R \), and the variation 1 of the Brans-Dicke scalar. The behaviour of the mass function, in the integration domain, is similar to the compact pulse case. There is a subtle difference in that ingoing (\( v = \text{constant} \)) observers see more mass in action than in the compact case. The curvature and Brans-Dicke scalar variations exhibit, on the other hand, a noticeable difference. For the non-compact in ux they are monotonic functions of \( v \), for large \( u \), whereas for the compact pulse, they stop growing at some \( v \) and resume growing for larger \( v \). The transition seems to be associated to the end of accretion.

V. Conclusions

We have studied the internal structure of spherical charged black holes in the framework of the Brans-Dicke theory of gravity, together with the variations of the Brans-Dicke scalar, which determines the gravitational coupling.

The initial expectations drawn from naive arguments given in the introduction suggested possible large variations of the Brans-Dicke scalar near the inner horizon of the black hole. The use of the homogenous approximation indicated that these expectations were correct: in a model with \( w = 0 \), the Brans-Dicke scalar had a divergent behaviour near the inner horizon. However, in a realistic scenario, accretion will generate counter-streaming and hence mass in action. In turn, mass in action changes the dynamics of the Brans-Dicke scalar and prevents large variations of this scalar from occurring. This conclusion was obtained by comparing the behaviour of models with \( w = 0 \) and \( w = 1 \). We emphasize that the non-existence of mass in action in a single-model with \( w = 0 \) is unrealistic, because even the tiniest admixture of a second-uid would allow relativistic counter-streaming and therefore mass in action to occur.

One counter-intuitive result drawn from the homogeneous approximation is that mass in action is one abrupt for a smaller value of the initial perturbation, in agreement with the conclusions of [16]?

We have performed full non-linear numerical simulations of the evolution of the black hole perturbed by both a compact and a non-compact in ux. In the case of the compact pulse, one observes some (expected) changes in the black hole interior, namely the growth of the outer horizon, decrease of one of the light-like sheets of the inner horizon and exponential growth of the effective mass function and curvature near the other light-like sheet of the inner horizon. In this case, the black hole settles down after accretion to a new stationary state, as illustrated in the Carter-Penrose diagram in Fig. 10. The relative variations of the Brans-Dicke scalar are small (between \( 10^{-6} \) and \( 10^{-7} \)) in the integration region when the compact pulse increases the black hole mass by around 1%. These variations grow slowly towards the Cauchy horizon, but seem to stabilize. The end of accretion is noticeable, in the case of a compact in ux, in both the curvature and the Brans-Dicke scalar variations.

For a non-compact pulse, on the other hand, the black hole does not settle down to a stationary state. This is a more realistic scenario, since real black holes are not expected to stay isolated forever, after an initial accretion period. For this type of perturbation, the changes in the black hole structure are similar to those of a compact in ux. Noticeable qualitative differences appear, however, in the curvature and the Brans-Dicke scalar variations. For an accreted mass of around 1% of the black hole mass (in the time spanned by the simulation) these variations are still small, albeit around one order of magnitude larger than for the compact pulse.
