Black holes in equilibrium can be defined locally in terms of the so-called isolated horizon boundary condition given on a null surface representing the event horizon. We show that this boundary condition can be treated in a manifestly SU(2) invariant manner. Upon quantization, state counting is expressed in terms of the dimension of Chern-Simons Hilbert spaces on a sphere with punctures. Remarkably, when considering an ensemble of fixed horizon area $a_H$, the counting can be mapped to simply counting the number of SU(2) intertwiners compatible with the spins labelling the punctures. The resulting BH entropy is proportional to $a_H$ with logarithmic corrections $\Delta S = -\frac{3}{2}\log a_H$. Our treatment from first principles settles previous controversies concerning the counting of states.

PACS numbers:

Black holes are intriguing solutions of general relativity describing the physics of gravitational collapse. These fascinating systems—whose existence in our universe is supported by a great amount of observational evidence—are remarkably simple. However, in the interior of the event horizon, the predictive power of classical general relativity breaks down due to the unavoidable appearance of un-physical divergences of the gravitational field (singularities). Dimensional arguments imply that quantum effects cannot be neglected near singularities. In this precise sense, black holes (BH) provide the most tantalizing theoretical evidence for the need of a more fundamental (quantum) description of the gravitational field.

Quantum effects are also important outside the horizon. Indeed the semiclassical calculations of Hawking [1] show that BH’s radiate as perfect black bodies at temperature proportional to their surface gravity and have an entropy $S = a_H/4\ell_p^2$, where $\ell_p^2 = \hbar G/c^3$ is the Planck area. This entropy is expected to arise from the huge number of microstates of the underlying fundamental quantum theory describing the BH, and therefore its computation from basic principles is an important test of any candidate quantum theory of gravity. This letter proposes a new and more fundamental framework for the computation of BH entropy in loop quantum gravity (LQG) and establishes a precise relationship between SU(2) Chern-Simons (CS) theory and quantum black hole physics as first explored in [2].

Our treatment clarifies the description of both the classical as well as the quantum theory of black holes in LQG making the full picture more transparent. We show that, in contrast with prior results [2], the gauge symmetry of LQG need not be reduced from SU(2) to U(1) at the horizon. Even when the U(1) reduction is perfectly valid at the classical level, it leads to imposition of certain components of the quantum constraints only in a weak sense. Our SU(2) invariant formulation—equivalent to the U(1) at the classical level—avoids this issue and allows the imposition of the constraints strongly in the Dirac sense. This leads to a drastic simplification of the quantum theory in which states of a black hole are now in one-to-one correspondence with the fundamental basic volume excitations of LQG given by single intertwiner states. This settles certain controversies concerning the relevant quantum numbers to be considered in the counting of states. The main quantitative result of our work is the correction of the value of the BH entropy.

The standard definition of a BH as a spacetime region of no escape is a global definition. This notion of BH requires a complete knowledge of a spacetime geometry and is therefore not suitable for describing local physics. This is solved by using instead the notion of isolated horizons (IH): defined by extracting from the definition of a Killing horizon the minimum conditions necessary for the laws of BH mechanics to hold [3]. They may be thought of as “apparent horizons in equilibrium”. Even though IH are very general, allowing rotation and distortion, for simplicity here we concentrate on the case in which the horizon geometry is spherically symmetric. In the vacuum case, the latter are easy to visualize in terms of the characteristic formulation of general relativity with initial data given on null surfaces: spacetimes with such IH are solutions to Einstein’s equations where Schwarzschild data are given on the horizon and suitable free radiation is given at a transversal null surface [3] (see Fig. 1).

The calculation of black hole entropy in LQG is done by quantizing the sector of the phase space of general relativity corresponding to solutions having an IH. At the technical level this sector is defined by postulating the existence of a null boundary $\Delta \subset M$ with topology $S^2 \times \mathbb{R}$ with the pull-back of the gravitational field to $\Delta$ satisfying the isolated horizon boundary conditions.

It is well known that the initial value formulation of general relativity can be characterized in terms of a triad field $e^a_i$ through $\Sigma = e_i \wedge e$—encoding the intrinsic spatial metric of $M$ as $q_{ab} = e^i_a e^i_b \delta_{ij}$—and certain components of...
the extrinsic curvature $K_{ab}$ of $M$ defined by $K^i_a = K_{ab} e^b_i$. It can be shown that the symplectic structure of gravity

$$\Omega_M(\delta_1, \delta_2) = \frac{1}{8\pi G} \int_M [\delta_1 \Sigma^i \wedge \delta_2 K^i_a - \delta_2 \Sigma^i \wedge \delta_1 K^i_a]$$

(1)
is preserved in the presence of an IH. More precisely in the shaded space-time region in Fig. 1 one has

$$\Omega_{M_1}(\delta_1, \delta_2) = \Omega_M(\delta_1, \delta_2).$$

(2)

That is, the symplectic flux across the isolated horizon $\Delta$ vanishes due to the isolated horizon boundary condition \[4\][5]. One also has that, on shell, phase space tangent vectors $\delta_\alpha, \delta_\epsilon$ of the form

$$\delta_\alpha \Sigma = [\alpha, \Sigma], \quad \delta_\alpha K = [\alpha, K]; \quad \delta_\epsilon \Sigma = \mathcal{L}_\epsilon \Sigma, \quad \delta_\epsilon K = \mathcal{L}_\epsilon K$$

for $\alpha : M \to \mathfrak{su}(2)$ and $\epsilon \in \text{Vect}(M)$ tangent to the horizon, are degenerate directions of $\Omega_M$ from which one concludes that $SU(2)$ triad rotations and diffeomorphisms are gauge symmetries \[7\]. Hence, the IH boundary condition breaks neither the symmetry under these diffeomorphisms nor the $SU(2)$ internal gauge symmetry introduced by the use of triad variables.

![FIG. 1: The characteristic data for a (vacuum) spherically symmetric isolated horizon corresponds to Schwarzschild data on $\Delta$, and free radiation data on the transversal null surface.](image)

Ashtekar-Barbero connection variables are necessary for the quantization à la LQG. When there is no boundary the $SU(2)$ connection

$$A^i_a = \Gamma^i + \beta K^i_a$$

(3)
is canonically conjugate to $e^{abc} \beta^{-1} \Sigma^b_c / 2$ where $\beta$ is the so-called Immirzi parameter. As shown below, in the presence of a boundary the situation is more subtle: the symplectic structure acquires a boundary term $\Omega_H$. Due to the fact that, at the horizon, phase space tangent vectors $\delta$ are linear combinations of $SU(2)$ gauge transformations and diffeomorphisms tangent to the horizon $H = M \cap \Delta$, the boundary term $\Omega_H$ is completely fixed by the requirement of gauge invariance, i.e., the condition that local $SU(2)$ transformations, now taking the form

$$\delta_\alpha \Sigma = [\alpha, \Sigma], \quad \delta_\alpha A = -d_A \alpha$$

(4)
as well as diffeomorphisms preserving $H$, continue to be degenerate directions of the symplectic structure. The symplectic structure, in the new variables, becomes \footnote{1}{This follows firstly from $\Omega_M(\delta_\alpha, \delta_\epsilon) = 0$ implying $-\kappa \Omega_H = \int_M [\delta_\alpha \Sigma^i \wedge \delta \delta A^i - \delta_\alpha \Sigma^i \wedge \delta_\epsilon \delta A^i] = \int_M [\delta_\alpha \Sigma^i \wedge \delta \delta A^i + \delta_\epsilon \delta A^i \wedge d_A \alpha^i] = \int_M d(\alpha_\delta \delta \Sigma^i) - \alpha_\epsilon d(\delta \delta \Sigma^i) = -\frac{a_H}{\pi(1 - \beta^2)} \int_M \delta_\alpha F^i(A) = \frac{a_H}{\pi(1 - \beta^2)} \int_M \delta_\alpha A^i \wedge \delta \delta A^i.$}

$$\kappa \Omega_H = \int_M [2 \delta_\alpha_1 \Sigma^i \wedge \delta_\alpha_2 \delta_\alpha A^i - \frac{a_H}{\pi(1 - \beta^2)} \int_M \delta_\alpha A^i \wedge \delta_\alpha_2 A^i],$$

(5)

where $\kappa = 8\pi G \beta, a_H$ is the horizon area, and we have used the IH boundary condition which in terms of Ashtekar-Barbero variables is found \[8\] to take the form

$$\Sigma^i + \frac{a_H}{\pi(1 - \beta^2)} F^i(A) = 0.$$  

(6)

Note that the boundary contribution to the symplectic structure is given by an $SU(2)$ CS symplectic form. One can also show directly that the boundary term contribution is necessary for time evolution to preserve the symplectic form.

Another consequence of the fact that $SU(2)$ transformations and diffeomorphisms preserving $H$ are gauge is that (in the canonical formulation) they are Hamiltonian vector fields generated by first class constraints. More precisely one has that

$$\Omega(\delta_\alpha, \delta_\epsilon) + \delta G(\alpha, A, \Sigma) = 0,$$

$$\Omega(\delta_\alpha, \delta_\epsilon) + \delta V(\epsilon, A, \Sigma) = 0,$$

(7)

where $G$ and $V$ are the Gauss and Diffeo constraint bulk-terms, plus boundary-terms.
operators
conical singularities of strength encoded in the quantum
of the (quantum) CS connection vanishes everywhere on
where we have ignored the Poisson brackets involving the
scalar constraint as its smearing must vanish on $H$, i.e.,
it does not affect the first class nature of the previous
constraints. Thus (10) are first class constraints and can
be implemented à la Dirac in the quantum theory.

This fact and the form of the symplectic structure moti-
vates one to handle the quantization of the bulk and
horizon degrees of freedom (d.o.f.) separately. As in
standard LQG [8] one first considers (bulk) Hilbert spaces
$\mathcal{H}^B_\gamma$ defined on a graph $\gamma \subset M$ with end points on $H$,
denoted $\gamma \cap H$. The quantum operator associated with
$\Sigma$ in (7) is
\[
\varepsilon_l^a \delta_{\gamma p}(x) = 8\pi G\beta \sum_{p \in \gamma \cap H} \delta(x, x_p) J^l(p)
\]
where $[J^l(p), J^j(p)] = \varepsilon^l_{ij} J^j(p)$ at each $p \in \gamma \cap H$. Con-
sider a basis of $\mathcal{H}^B_\gamma$ of eigen-states of both $J^l_p, J^j_p$ as well
as $J^j_p$ for all $p \in \gamma \cap H$ with eigenvalues $h^2 J^j_p(j_p + 1)$ and
$m_p$ respectively. These states are spin network states,
here denoted $|\{j_p, m_p\}_\gamma^\ast; \ldots\rangle$, where $j_p$ and $m_p$ are the
spins and magnetic numbers labeling $n$ edges puncturing
the horizon at points $x_p$ (other labels are left implicit).
They are also eigenstates of the horizon area operator $a_H$
\[
a_H|\{j_p, m_p\}_\gamma^\ast; \ldots\rangle = 8\pi \beta \ell_p^2 \sum_{p=1}^n \sqrt{J_p(j_p + 1)} |\{j_p, m_p\}_\gamma^\ast; \ldots\rangle.
\]

We can decompose $\mathcal{H}^B_\gamma$ according to
\[
\mathcal{H}^B_\gamma = \bigoplus_{\{j_p\} \in \gamma \cap H} \mathcal{H}^B_\gamma(\{j_p\})
\]
for spaces $\mathcal{H}^B_\gamma(\{j_p\})$ spanned by states $|\{j_p, m_p\}_\gamma^\ast; \ldots\rangle$ for
a given $n$-tuple $\{j_p\}$.

Substituting the expression (9) into (7) we get
\[
-\frac{a_H}{\pi(1-\beta^2)} \varepsilon_{ab} \hat{F}^c_{ab} = 8\pi G\beta \sum_{p \in \gamma \cap H} \delta(x, x_p) J^l(p)
\]
This equation tells us that the surface Hilbert space,$\mathcal{H}^S_\gamma H$ is precisely the one corresponding to (the well
studied [8]) SU(2) CS theory in the presence of particles
with CS level $k = a_H/(2\beta(1-\beta^2)\ell_p^2)$. The curvature of the (quantum) CS connection vanishes everywhere on
$H$ except at the position of the defects where we find
conical singularities of strength encoded in the quantum
operators $J^j_p$.

The solutions of (11) restricted to the graph $\gamma$ are
found to be elements of the Hilbert space $[8]$.
\[
\mathcal{H}_\gamma = \bigoplus_{\{j_p\} \in \gamma \cap H} \mathcal{H}^{inv}_\gamma(\{j_p\}) \otimes \mathcal{H}^{CS}_k(\{j_p\}),
\]
where $\mathcal{H}^{inv}_\gamma(\{j_p\})$ is a proper subspace of $\mathcal{H}^B_\gamma(\{j_p\})$
spanned by area eigenstates, and $\mathcal{H}^{CS}_k(\{j_p\})$ are the CS
Hilbert spaces which turn out to be completely deter-
mined by the total spin of punctures $\{j_p\}$ [8]. The full
Hilbert space of solutions of (11) is obtained as the pro-
jective limit of the spaces $\mathcal{H}_\gamma$. The IH boundary con-
dition implies that lapse must be zero at the horizon so
that the scalar constraint is only imposed in the bulk.
The entropy of the IH is computed by the formula
$S = tr(\rho_{IH} \log \rho_{IH})$ where the density matrix $\rho_{IH}$ is
obtained by tracing over the bulk d.o.f., while restricting
to horizon states that are compatible with the macro-
sopic area parameter $a_H$. Assuming that there exist
at least one solution of the bulk constraints for every ad-
missible state on the boundary, the entropy is given by
$S = \log(\mathcal{N})$ where $\mathcal{N}$ is the number of horizon states
compatible with the given macroscopic horizon area $a_H$.
After a moment of reflection one sees that
\[
\mathcal{N} = \sum_{n(\{j\}_n)} \dim[\mathcal{H}^{CS}_k(j_1 \cdots j_n)],
\]
where the labels $j_1 \cdots j_p$ of the punctures are constrained
by the condition
\[
a_H - \epsilon \leq 8\pi \beta \ell_p^2 \sum_{p=1}^n \sqrt{J_p(j_p + 1)} \leq a_H + \epsilon.
\]
Similar formulae were first used in [8].

It turns out that due to (14) we can compute the
entropy for $a_H >> \beta \ell_p^2$ (not necessarily infinite).
The reason is that the representation theory of $U_q(SU(2))$—
describing $\mathcal{H}^{CS}_k$ for finite $k$—implies
\[
\dim[\mathcal{H}^{CS}_k(j_1 \cdots j_n)] = \dim[\text{Inv}(\otimes \rho_{p,j})],
\]
as long as all the $j_p$ as well as the interwining internal
spins are less than $k/2$. But for Immirzi parameter in
the range $[\beta] \leq 3$ this is precisely granted by [11] [8].
All this simplifies the entropy formula considerably.

The previous dimension corresponds to the number of
independent states one has if one models the black hole
by a single SU(2) intertwiner!

Let us conclude with a few remarks.

We have shown that the spherically symmetric isolated
horizon is described by a symplectic form $\Omega_M$ that, when
written in the (connection) variables suitable for quanti-
zation, acquires a horizon contribution corresponding to
an SU(2) CS theory. Our derivation of the (conserved)
symplectic structure is straightforward. We first observe
that SU(2) and diffeomorphism gauge invariance is not
broken by the IH boundary condition: they continue to
be degenerate directions of $\Omega_M$ on shell. This by itself
is then sufficient for deriving the boundary term that
fixes the geometry at $\Delta$ (the IH condition allows a single
(characteristic) initial data once $a_{ij}$ is fixed (see fig. 1). Nevertheless, non trivial d.o.f. arise as would be gauge d.o.f. upon quantization. These are described by $SU(2)$ CS theory with (an arbitrary number of) defects which couple to gauge d.o.f. through the dimensionless parameter $16\pi^2\beta(1-\beta^2)/a_{ij}^2$, i.e., the ratio of a basic quantum of area carried by the defect to the total area of the horizon. These would be gauge excitations are entirely responsible for the entropy.

We obtain a remarkably simple formula for the horizon entropy: the number of states of the horizon is simply given in terms of the (well studied) dimension of the Hilbert spaces of CS theory with punctures labeled by spins, which—due to the area constraint (14), and for the range $|\beta|<\sqrt{3}$ including the physical value of $\beta$ (13)—is just the dimension of the singlet component of the tensor product of the representations carried by punctures. The black hole density matrix $\rho_H$ is the identity on $\text{Inv}(\otimes_p j_p)$ for admissible $j_p$. Similar counting formulae have been proposed in the literature (10) by means of heuristic arguments. Our derivation from first principles in particular clarifies previous proposals.

General arguments and simple estimates indicate that the entropy will turn out to be $S_{BH}=\beta_0 a_H/(4\beta_0^2)$, where $\beta_0$ is a constant to be determined. The new counting techniques of (12) are expected to be very useful for this. Thus the result to leading order remains unchanged. However, subleading corrections will have the form $\Delta S=-\frac{1}{2}\log a_H$ (instead of $\Delta S=-\frac{1}{2}\log a_H$ in the $U(1)$ treatment) matching other approaches (11). This is due to the full $SU(2)$ nature of the IH quantum constraints imposed here, and this is a clear-cut indication that the $U(1)$ treatment overcounts states. The value $\beta_0$ and the log-correction has been recently computed for $|\beta|<\sqrt{3}$ (13). The range $|\beta|\geq\sqrt{3}$ is unphysical as the quantum group structure imposes additional constraints driving the entropy below the physical value $a_{ij}/4$.

In ref. (1) the classical description of the IH was first done in terms of the null tetrad formalism. In this case the null surface defining the Horizon provides the natural structure for a partial gauge fixing from the internal gauge $SL(2,\mathbb{C})$ to $U(1)$. In this setting one fixes an internal direction $r^i\in su(2)$ and the IH boundary condition (32) becomes

$$dV+\frac{2\pi}{a_{ij}}\Sigma^i x_i=0,\quad \Sigma^i x_i=0,\quad \Sigma^i y_i=0,$$

where $x^i, y^i\in su(2)$ are arbitrary vectors completing an internal triad. In the quantum theory (2) only the first of the previous constraints is imposed strongly, while—due to the non-commutativity of $\Sigma^i$ in LQG—the other two can only be imposed weakly, namely in (2) one has $\langle \Sigma^i x_i \rangle = \langle \Sigma^i y_i \rangle = 0$. However, this leads to a larger set of admissible states (over counting). To solve this problem, within the $U(1)$ model, one would have to solve the two constraints $\Sigma^i x_i = 0 = \Sigma^i y_i$ at the classical level first, implementing the reduction also on the pull back of two forms $\Sigma^i$ on $H$. However, this would introduce formidable complications for the quantization of the bulk degrees of freedom in terms of LQG techniques. Our $SU(2)$ treatment resolves this problem as now the three components of (9) are first class constraints. Dirac implementation leads to a smaller subset of admissible surface states that are relevant in the entropy calculation.
