Constraints on cosmic hemisphical power anomalies from quasars

E-mail: chirata@tapir.caltech.edu

Abstract. Recent analyses of the cosmic microwave background (CMB) maps from the WMAP satellite have uncovered evidence for a hemispherical power anomaly, i.e. a dipole modulation of the CMB power spectrum at large angular scales with an amplitude of 14 percent. Erikcek et al have put forward an in ationary model to explain this anomaly. Their scenario is a variation on the curvaton scenario in which the curvaton possesses a large-scale spatial gradient that modulates the amplitude of CMB fluctuations. We show that this scenario would also lead to a spatial gradient in the amplitude of perturbations \(s\), and hence to a dipole asymmetry in any highly biased tracer of the underlying density field. Using the redshifted quasars from the Sloan Digital Sky Survey, we nd an upper limit on such a gradient of \(s\) \(\lesssim 0.027 \pm 0.007\) \((99\%\) posterior probability), where \(s\) is the comoving distance to the last-scattering surface. This rules out the simplest version of the curvaton spatial gradient scenario.

1. Introduction

The simplest in ationary models for the origin of structure of the Universe have made a number of successful predictions, including the atness of the Universe \((\Omega = 0)\), and near-scale invariance \((\sigma_8 = 1)\), adiabaticity, and Gaussianity of the primordial fluctuations. A nother prediction of these models is that the perturbations should be statistically homogenous and isotropic. It was therefore a surprise when, after the cosmic microwave background (CMB) maps from the Wilkinson Microwave Anisotropy Probe (WMAP) satellite were released \([1, 2, 3]\), several groups reported evidence for large-scale anomalies in the data that were suggestive of inconsistencies with the paradigm of a statistically isotropic Gaussian random eld, or with the theoretical power spectrum. One widely discussed anomaly was an alignment of some of the low multipoles with a so-called Axis of Evil \([4, 5, 6, 7]\). Another was the CMB quadrupole \(C_2\), which was unexpectedly low for the standard cosmological model \([8]\). A third anomaly was a difference in the observed CMB power spectrum between two hemispheres \([9, 10, 11, 12]\). A variety of theoretical explanations for these anomalies have been proposed \([13, 14, 15, 16, 17, 18, 19, 20]\).

The hemisphrical power anomaly is the main subject of this paper. Its properties, as measured by Hennawi et al \([12]\), can be summarized as follows: (1) The direction of greatest power is \(\hat{\beta} = (1\beta) = (224, 22)\), near the South Ecliptic Pole. (2) The amplitude of large-scale fluctuations \((\sigma_8 = 64)\) is \(A = 0.072 \pm 0.022\), meaning that the amplitude of the CMB perturbations \(s\) is 1.07 times the mean.
value in the $\phi$ direction, and 0.93 times the mean value in the $\theta$ direction. \(3\)

The asymmetry is present in at least three of the WMAP bandpasses (41, 61, and 94 GHz), and in the foreground-suppressed internal linear combination (ILC) map \(21\).

(4) Only limited information is available about the $\ell^2$-dependence of the asymmetry. There are indications that it continues at least to $\ell \approx 80 \[12\]$ and perhaps beyond \[11\], but other analyses have found no evidence for an amplitude asymmetry at the first acoustic peak \[28\].

The large-scale asymmetries are a difficult subject, in part because there is no clean way to assess their true significance. While the quoted significances sometimes exceed 95\%, some of the analyses are a posteriori. In order to make progress it is necessary to consider the theoretical explanations for the large-scale asymmetries, and ask what new predictions these models yield \[22\]. For some of the proposed ideas that only affect the low multipoles, the CMB temperature map has reached its com $\sim$ 3% variance limit and further tests must await future CMB polarization data with lower noise and foreground residuals than WMAP. On the other hand, one class of models intended to explain the hemispheric power asymmetry make a host of new predictions testable with near-future or even current data. Erickcek et al \[20\] recently proposed a variation on the curvaton model \[23,24,25,26\]: an in atom, which dominates the energy density during inflation, and a curvaton, which is effectively massless during inflation but decays after inflation ends to produce a density $\rho$.

In the variation of Erickcek et al \[20\], there was initially a large-scale gradient in $\rho$; since the primordial density perturbations are proportional to $\ell^2$ (assuming they are sourced by the curvaton) and neutron-induced density perturbations may also be significant), the amplitude of the density perturbations is statistically inhomogeneous, being proportional to the local value of $\rho$. A uniform gradient in the background $\rho$ then results in a dipole modulation of the CMB power spectrum in the direction of $\phi = k \pi j \rho$ with an amplitude given by the fractional variation of across our horizon volume $e$.

As noted by Erickcek et al \[20\], the proposed model could be tested with future CMB data, especially with the upcoming Planck satellite, which will observe many more modes in the CMB than WMAP and should be relatively clean or reject the power spectrum asymmetry possibly seen by WMAP. (The model could possibly even be constrained further by using the higher multipoles in WMAP.) However such a model also makes predictions for large-scale structure: since the dipole asymmetry in the power spectrum varies slowly with wavenumber $k$, it generates a large-scale gradient in the amplitude of fluctuations $\delta$. Thus the abundance of rare massive haloes should contain a spatial gradient. Thus the angular distribution of these massive haloes (or any luminous tracer thereof) should contain a dipole in the same direction $\phi$ singled out by the CMB. Moreover, using the measured dipole anisotropy of the CMB power spectrum and our knowledge of the halo mass function, one can speculatively predict the amplitude of these features as a function of redshift and halo mass. Such features, if detected with the correct dependences and alignment of the CMB, would be a smoking gun for new physics, whereas nondetection of the large-scale structure dipole would rule out the simplest version of the Erickcek et al \[20\].

\[3\] The asymmetry in the C$_3$S is twice this, 14% percent, since the power spectrum is the square of the amplitude.

\[x\] We have assumed here that the curvaton never contributes more than a small fraction of the energy density of the Universe; this is true in the Erickcek et al model, but it is not true in all curvaton models.
The purpose of this paper is two-fold: first, to develop the formalism to test for
a spatial gradient in \( \theta \); and second, to apply this formalism to the current large-
scale structure data and measure \( \theta \). Our primary motivation was the Erikocek et al. \[20\] model, but we note that any early-Universe explanation for the hemispherical asymmetry is likely to produce \( \theta \) and hence our measurement should provide tight
constraints. [We note that a statistically anisotropic power spectrum \( P(k) \) cannot
produce the dipole signature seen by Refs. \[8,10,11,12\] because it is invariant under
\( k \rightarrow -k \).] For our measurement of \( \theta \), we use the high-redshift spectroscopic quasars
from the Sloan Digital Sky Survey (SDSS) as described below.

2. Theory

2.1. The Model

The Erikocek et al. \[20\] model produces a local primordial fluctuation amplitude
\( R(k) \) that has a spatial gradient:

\[
R(k; r) = R(k; 0) \left( 1 + \frac{r}{r_{\text{ls}}}ight); \tag{1}
\]

where \( r_{\text{ls}} \) is the distance to the surface of last scattering. This normalization was
chosen so that in observations of the CMB the amplitude of variations is modulated
by a factor \( 1 + A \cos \theta \) where \( \theta \) is the angle between the gradient direction \( \hat{\theta} \) and the
line of sight \( \hat{r} \) and \( A = p \hat{\rho} \) (with \( m \) norm modulations due to reionization, see below).
Constraints in this paper will be reported on the amplitude \( A \) and direction \( \theta \) of this
modulation.

2.2. Eect on CMB

A large-scale gradient in the primordial fluctuation amplitude will produce a corresponding dipole in the CMB anisotropies. On small scales, where the added power from the integrated Sachs-Wolfe (ISW) effect and reionization are negligible, the local CMB power spectrum in a particular region of the sky \( \hat{\theta} \) is

\[
C_{1\text{loc}}(\hat{\theta}) = C_1 \exp^{2(\theta_n)(1 + p \hat{\rho})^2}; \tag{2}
\]

where \( \theta_n \) is the change in optical depth in direction \( \theta \) relative to the reference
model. There is motivation for such a term to exist: if \( \theta \) is larger in some regions
than others, the regions of higher \( \theta \) will form more early galaxies and we expect that
they will reionize rst. In the case where \( A \) is small, we may write:

\[
C_{1\text{loc}}(\theta) = C_1 (1 + 2X p \hat{\rho}); \tag{3}
\]

where the factor

\[
X = 1 + \frac{r_{\text{ci}} d}{r_{\text{ls}} d \ln \theta}; \tag{4}
\]

accounts for the increase of \( \theta \) and hence in direction \( +\hat{\rho} \) versus \( \hat{\rho} \), and the factor
\( r_{\text{ci}} = r_{\text{ls}} \) accounts for the fact that the reionization surface is closer to us than the last
scattering surface. Reionization occurs during the matter-dominant era when the
optical depth depends on the scale factor at reionization \( a_{\text{ci}} \) via \( \theta_n \). Therefore

\[
X = 1 + \frac{3}{2} \frac{r_{\text{ci}} d \ln a_{\text{ci}}}{2r_{\text{ls}} d \ln \theta}; \tag{5}
\]
Hemispherical anomalies

From the WMAP 5-year parameter constraints we know that $\Delta = 0.087 \pm 0.012$ and $3 \ln \rho_{cd} = 2.25 \pm 0.27$. One does not know $\ln a = \ln a$, as this depends sensitively on astrophysics. If reionization is caused by massive haloes, so that the dependence of the reionization redshift on $\delta$ is dominated by changes in the halo mass function, then we have $a = \frac{1}{\delta}$ because the halo mass function during the matter-dominated era is invariant under rescalings of $a$ and $\delta$ that hold $\delta a$ constant. This case gives $\ln a = \ln a = 1$, i.e., higher $\delta$ gives earlier reionization. This number will be increased somewhat (i.e., made closer to zero) if one takes into account that at earlier times some photons are required to reionize the intergalactic medium because of recombinations. It will also be increased if higher $\delta$ implies a larger clumping factor, or more massive haloes that act as a sink for ionizing photons. While the astrophysics is unclear at present, we are fortunate that the multiplying factor of $0.09$ renders $X$ relatively insensitive to the details: the $\ln a = \ln a = 1$ case would imply $X = 0.91$, whereas the extreme case of assuming reionization at an epoch independent of $\delta$ would give $X = 1$. For practical purposes $X = 1$ with negligible correction (unless the anisotropy is measured at $10^{-2}$) and we will not consider it further.

The power asymmetry analysis of Ref. [10] using the 3-year WMAP data and a range of scales $2 \leq \ell \leq 40$ found an asymmetry of $A = 0.114 \pm 0.022$ at the direction $\hat{\Omega} = (225^\circ, 27^\circ)$ and 99.1% significance. A more recent analysis by Hansen et al. [11] using the 5-year WMAP data and going out to $m_{\max} = 600$ nds preliminary evidence for a direction of $\hat{\Omega} = (226^\circ, 17^\circ, 10^\circ)$ at 99.6% significance. Very recently, Hui et al. [12] search the range of scales up to $m_{\max} = 64$ and find a 3.3 dipole, $A = 0.072 \pm 0.022$ with $\eta = (224^\circ, 22^\circ, 24^\circ)$ in the WMAP 5-year ILC map. In the 61 GHz band, they carried the analysis up to $m_{\max} = 80$ and found $A = 0.019 (3.7^\circ)$ at $99.1\%$ significance. A more recent analysis by Donoghue [28] of the first acoustic peak finds a power spectrum asymmetry of $A = 2A = 0.002 \pm 0.002$ at $m_{\max} = 500$ (assuming the direction $\hat{\Omega}$ given by Hansen et al. [3]), in plying $A < 0.03$ at $2\sigma$. This is in tension with the low-$\ell$ results, and motivates further analysis to reduce the uncertainty on $A$.

One way to reduce the error bars on the CMB method would be to extend it to higher $\ell$ where there are more modes available to constrain the hemispherical asymmetry. The number of CMB modes available is proportional to $\ell_{\max}^2$ and so we would expect the uncertainty in $A$ to decrease as $\ell_{\max}^2$; the Hui et al. uncertainties are in rough agreement with this expectation. Extrapolating this scaling, an analysis making use of the full WMAP data out to $\ell_{\max} = 500$ should be able to reach $A = 0.003$ if other sources of uncertainty (e.g., unasked point sources) can be overcome. We believe such an analysis would be very helpful, especially to constrain the scale dependence of the asymmetry. However, in this paper we take an independent approach with similar sensitivity: we look for an asymmetry in large-scale structure.

### 2.3. Effect on large-scale structure

The large-scale gradient in $\delta$ also has an effect on the abundance of massive haloes and any objects that occupy them. For objects at a distance $r$, the observed 2-dimensonal number density varies across the sky as:

$$\frac{N}{N} (R) = \frac{r}{r_{\text{circ}}} \frac{\delta}{\ln N} \rho (r)$$

(6)
Our major problem here is determining $@\ln N>@\ln \delta$. This problem has been considered in the context of non-Gaussianity searches \cite{29,30,31}, which found

$$\frac{@\ln N}{@\ln \delta} = c(b^{-1});$$

(7)

where $c = 1.69$ and $b$ is the bias. This formula assumed a universal mass function, as found in simulations, and assumed that the objects under study have a halo occupation distribution (HOD) that depends only on halo mass. The dependence on $\delta$ makes conceptual sense: very massive objects are highly biased $b(M) \gg 1$, and their abundance increases rapidly with $\delta$; low-mass objects are anti-biased $b(\delta) < 1$ and are less abundant at high $\delta$ because they will have merged; and the overall abundance of dark matter particles with $b = 1$ does not depend on $\delta$. If only recent major mergers are occupied, then there is an additional suppression in Eq. (7) because massive halos form earlier if $\delta$ is increased. In the extended Press-Schechter (ePS) formalism, $b = 1$ should then be replaced by $b^{-1} = b^{-1} = 1.59$ \cite{32}; this exponent has been confirmed by re-scaling of simulations \cite{32,33} which suggest that during the matter-dominated era the $\delta$ dependence for recent major mergers ranges between $b = 1.59$ and $b = 1.65$ depending on the remnant mass and progenitor mass ratio \cite{31}. In the case of the SDSS quasars it is not clear what is the correct way to populate halos and so both limiting cases ($b = 1$ and $b = 1.6$) must be considered. In practice the bias of the high-redshift quasars is so large (10) that the difference between these cases is negligible.

In practice the quasars occupy a range of redshifts and the observed dipole is a superposition: $N = N = d \cdot$, where

$$d = c_p \int_{\delta_{\text{min}}}^{\delta_{\text{max}}} \delta P(\delta) d\delta;$$

(8)

with the replacement $b = 1!b = 1.5$ in the recent major merger case. Here $P(\delta)$ is the redshift distribution of the quasars, normalized to unity: $\int P(\delta) d\delta = 1$.

3. Application to SDSS quasars

We now turn to empirical determination of $\delta$ using the above formalism.

3.1. Choice of dataset

The high-redshift spectroscopic quasars from SDSS were chosen for this study because:

(i) They are very distant, which means that the same spatial gradient in $\delta$ translates into a large absolute difference across the sky.

(ii) They have wide angular coverage, which means large-scale structure noise and provides the leverage in all three Cartesian coordinates necessary to measure a dipole.

(iii) They are highly biased, so that a small change in $\delta$ is amplified into a much larger change in the number density of quasars.

(iv) They have very good rejection of Galactic objects (e.g. halo stars), which could otherwise produce spurious large angular scale modulation and potentially correlate with foreground residuals in the CMB maps.

(v) The relative photometric calibration of SDSS is understood at the percent level (although this degrades to a few percent in the $u$ band).
Hemispherical anomalies

(vi) The number density of $1 \text{ deg}^2$, while not impressive, is acceptable given the above advantages. Given the choice between high number density of nearby objects with a weak dependence on $g$, or a low number density of distant objects that depends strongly on $g$, our preference is for the latter since Nature does much of the work to suppress systematics.

There are other data sets that could have been used instead to trace large-scale structure at moderate to high redshift. Possibilities include:

(i) Luminous red galaxies: These are abundant but current large-scale maps go out to only $z < 0.7$ [34], or 18% of the distance to the last-scattering surface, and the typical bias is small, $b \approx 1.2$.

(ii) Photometrically selected quasars: These have a higher number density ($50 \text{ deg}^2$), but at present the UV-based selection algorithm restricts this sample to $z < 2.5$ [35]. The bias is also much lower at these redshifts, $b \approx 2.8(2.8)$.

(iii) Hard X-ray background: The $2(8) \text{ keV}$ HEAO map has excellent sky coverage and perhaps the best-constrained dipole [47], but the redshift distribution is poorly known and the estimated bias is small and may be consistent with $b = 1$ [38], so it is not known how sensitive this is to $r_g$.

(iv) Radio sources: The NRAO VLA Sky Survey [39] sample has been used to probe them moderate redshift range $z \approx 1$, but its redshift distribution is still under debate [40,41,36]. More importantly the maps exhibit declination-dependent striping which is certainly a systematic artifact and precludes determination of the dipole [42].

(v) Lyman-$\alpha$ forest: A different approach would be to measure a fluctuation amplitude from the Lyman-$\alpha$ forest at the same redshift but with sightlines in different parts of the sky. The differential nature of the measurement would suppress many of the astrophysical systematics in e.g. $P(k)$ measurement from the Lyman-$\alpha$ forest. This approach was not taken here because the analysis would be much more complicated, but given the large number of observed modes in the Lyman-$\alpha$ forest it should be considered in the future.

3.2. Data description

The high-redshift quasars used here are obtained from the SDSS. The SDSS drift-scans the sky in five bands (ugriz) [43] under photometric conditions [44,45] using a 2.5-meter optical telescope [46] with 3 degree field of view camera [47] located in New Mexico, USA [44]. The photometric and astrometric calibration of the SDSS and the quality assessment pipeline are described by Refs. [48,49,50,51,52]. Bright galaxies [53], luminous red galaxies (LRGs) [54], and quasar candidates [55] are selected from the SDSS imaging data for spectroscopic follow-up [56].

The spectroscopic quasar sample used here was based on colour selection criteria described in Richards et al. [55]. The algorithm selects quasar candidates down to a limiting magnitude of $i = 19.1$ or $20.2$ (for high-$z$ quasars); a discussion of its completeness and accuracy can be found in Richards et al. [55]. A statistical sample of confirmed quasars was generated by Shen et al. [57], who removed from the sample regions with early versions of the target selection algorithm. Shen et al imposed a further cut on the quality of the imaging data used for target selection, dividing it into "good" and "bad" elds. As a test for systematic effects, their quasar clustering analysis was repeated with both the "good" elds only, and with "all" elds.
The Shen et al. [57] sample has a minimum redshift $z = 2.9$, due to the need in target selection to avoid Galactic late A/early F stars which have similar broadband colours to quasars at $z = 2.7$, and most objects are at $z < 4.5$ due to the declining luminosity function and increasing luminosity distance at high redshift. There are 4426 quasars in the 'all' sample (4041 deg$^2$) and 3846 in 'good' (3506 deg$^2$). The quasars undersample the density field at all scales, so that their power spectrum is dominated by Poisson noise.

Shen et al. specify a mask, which we have imported into Mangle [58, 59, 60]. Mangle is a suite of computer programs widely used in the large-scale structure community to manipulate complex masks, which it typically represents as spherical polygons (i.e., regions bounded by circular arcs). Mangle can carry out simple tasks on these masks such as unions and spherical harmonic transform computation; most importantly for us, it can generate catalogues of random points from within a given mask.

For this analysis, we have further split the quasars into a $2.9 < z < 3.5$ sample, and a $3.5 < z < 4.5$ sample.

3.3. Dipole anisotropy estimator

In general the quasar density in a given direction can be written as:

$$\frac{N}{N} (\hat{n}) = d \hat{n} + \sum_i k_i t_i(\hat{n}) + C; \quad (9)$$

Here $N$ is the mean number of quasars per steradian, $N$ is its fluctuation, $d$ is the dipole (which we wish to measure), $t_i(\hat{n})$ are possible systematics ten plates in the quasar maps (e.g., the extinction map), $k_i$ are the sensitivities of the quasar densities to these systematics, and $C$ is a mean zero set over which we must marginalize since the true mean number density of quasars is not known. This equation can be simply written as:

$$\frac{N}{N} (\hat{n}) = x^T M(); \quad (10)$$

where we have defined the vectors $x = (d; k_i; C)$ and $T(\hat{n}) = (\hat{n}; t_i(\hat{n}); 1)$. If Poisson noise dominates the uncertainty in $N = N$, so that the inverse variance per steradian is $N$, then the best linear unbiased estimator for $x$ is obtained via:

$$\hat{x} = F^{-1} g; \quad (11)$$

where

$$g_i = T_i(\hat{n}) N(\hat{n}) d d \hat{n} \quad (12)$$

and the Fisher matrix is

$$F_{ij} = N T_i(\hat{n}) T_j(\hat{n}) d d \hat{n}; \quad (13)$$

The covariance matrix of this estimator is $\text{Cov}(x) = F^{-1}$. The above equations are integrals over the survey area, but quasars are discrete objects and so it is easiest to replace the above results with summations over the quasars and random catalogues. We can do this by writing:

$$g_i = T_i(\hat{n}_R) \frac{N_R}{N} T_i(\hat{n}_R); \quad (14)$$
where \( r_D \) and \( r_R \) are the positions of the quasars in the real data, \( r'_{ \text{D}} \) and \( r'_{ \text{R}} \) are the positions of randomly generated points in the survey mask, and \( N_D \) and \( N_R \) are the number of quasars (data) and random points respectively. The Fisher matrix is:

\[
F_{ij} = \frac{N_D}{N_R} X \frac{T_i(r'_R)}{T_j(r'_R)}
\] (15)

We have generated random catalogues containing \( N_R = 10^6 \) points using Angle’s \textsc{rnsack} task \[56\], which is more than sufficient as their residual noise is negligible (< 1%) compared to the actual data.

### 3.4. Measured dipole anisotropy

We have applied the estimator Eq. (13) to the high-\( z \) SDSS quasar data. Four versions of the task were done, which differed by using the ‘\textsc{all}’ or ‘\textsc{good}’ mask, and by either including or not including the dust tem plate. The dust template used is the predicted reddening map of \( E(B-V) \) by Schlegel et al.\[59\] as a systematics template, which is appropriate if the extinction correction is not perfect. Errors correlated with the map could arise due to errors in the assumed extinction law \( A = E(B-V) \), miscalibration of the \( E(B-V) \) scale, or unusual quasar colours acting the extinction correction (e.g. if a bright emission line lies at the red end of the bandpass then the band-averaged correction may overcorrect for the extinction). The template amplitude \( k_{V}^{E(B-V)} \) could plausible be positive or negative depending on the amount of over- or undercorrection in different bands. Because most of the data lie in the Northern Galactic cap, there is a strong degeneracy between the component of the dipole perpendicular to the Galactic plane and the extinction correction, \( \text{Corr}(k_{V}^{E(B-V)}; \delta_{d}) = 0.85 \): either increasing \( \delta_{d} \) or decreasing \( k_{V}^{E(B-V)} \) would have the effect of enhancing the number density of objects near the NGP. This degeneracy could be broken in the future with more data in the southern patch. For the ‘\textsc{all}’ mask, we find template amplitudes of \( k_{V}^{E(B-V)} = 1.5 \) (low-\( z \)) and \( k_{V}^{E(B-V)} = 1.5 \) (high-\( z \)); these become 1.0, 1.3 and 3.5 for the ‘\textsc{good}’ mask. We regard the ts with the dust template as our primary result because correlation with dust is marginally detected at \( > 2 \) in one of the redshift slices.

The resulting dipole moments in the Galactic coordinate system are shown in Table 4. To be explicit, we have placed the \( x \) direction toward the Galactic centre, the \( y \) direction in the plane at \( \lambda = 90^\circ \), and the \( z \) direction toward the North Galactic Pole (NGP). Using the ‘\textsc{all}’ mask and no dust tem plate, one finds an intriguing 2.9 hint of \( \delta_{d} > 0 \) in the low-\( z \) quasars. However the fact that the preferred direction is very near the NGP (\( b = 80^\circ \)) is suspicious, and indeed this signal goes away if one restricts to ‘\textsc{good}’ els (significance drops to 1.8), uses the dust tem plate (1.4), or both (0.8).

In all cases the uncertainty in the dipole determination is at least several percent, so no correction for our own peculiar velocity \( v = c = 0.0012^\circ \) is necessary.

In addition to the Galactic dust, a second concern would be large-angle calibration errors, which can involve either ‘grey’ errors (in which all \( \nu \) bands move together) or colour calibration errors. We may do a simple assessment of the grey calibration error by comparing the target selection photometry to the uncalibrated photometry \[50\] obtained from the Shen et al. \[57\] catalogue, in \( i \) band as used for the \( u \) cut. The uncalibrated photometry is estimated to be accurate to 1%. We compare the

$$m^{\text{agnitude difference}}_i = i_{\text{target}} - i_{\text{bercal}}$$ for each quasar, and do an unweighted least-squares $t$

$$i = i_0 + m \hat{n}$$;  

(16)

where $m$ is the calibration dipole and $n$ is the position of that quasar. We removed two (possibly variable) objects from the total that were undetected in the ber calibrated photometry. The resulting dipole is $10^5 m = (0; 3; 10; 3; 3; 3)$. We have also tried clipping the distribution of $i$ at the 1st and 99th percentiles (i.e., quasars below the 1st percentile were moved to the 1st percentile value before clipping). The resulting dipole is $10^5 m = (0.0; 0.8; 3.5; 0.9; 0.5; 0.8)$. The implied dipole due to changes in the $i$ band calibration would be 1.8 times this, since the slope of the cumulative quasar luminosity function for this redshift range and the $i < 20.2$ UG cut is 1.8 (see e.g., Fig. 13 of Ref. [62]). Even the 1% dipole obtained from the first $t$ would lead to a calibration-induced dipole of 1.8% in the density of quasars, which is much less than our 5(10)% statistical errors. (But be sure that both calibration dipoles are inconsistent with zero, giving $\chi^2$ for 3 degrees of freedom of 12 and 19, respectively.)

Colour calibration is potentially nastier since quasars are selected by cuts that run through the quasar locus, and hence colors tend to result in completeness variations if there is a relative colour calibration error. Our best test of the colour-dependent calibration will be the agreement (or lack thereof) of the dipoles inferred from different redshift ranges where the colour selection is very different. However, we can also test for this by computing the dipole of the reddening-corrected colours, i.e., doing an unweighted least-squares $t$

$$u \ g = (u \ g_0) + m \hat{n}$$;  

(17)

where $(u \ g)$ and the vector $m$ represent 4 free parameters. We use all of the quasars in the $2 < z < 4$ range for this test. Since some quasars are undetected in $u$, we clip the distribution at the 5th and 95th percentiles in $u \ g$ before performing the $t$ (i.e., quasars below the 5th percentile were moved to the 5th percentile value before clipping). One can then test for whether $m \neq 0$, which would possibly indicate a dipole variation in colour calibration across the sky. We report the $\chi^2$ value, $m \ \text{Cov}_{m,n} \ m$, and the probability to exceed $P(> \chi^2)$. Similar tests can be done for the other colours, and for the extinction-corrected apparent magnitudes of the quasars. The magnitudes and colours used are those used for the target selection (TARGET PSF photometry), which were obtained via matching to the SDSS DRS5 quasar catalogue [63]. The results are shown in Table 2. As one can see, the $\chi^2$ values for these tests are all acceptable.
with one possible exception \( (r_{i}, p = 0.028) \). Given that we searched 10 directions in colour space, the presence of this one anomaly is unusually high \( ^2 \) value is not a concern.

### 3.5. Quasar bias and final results

In order to convert the measured dipole anisotropy into a constraint on the perturbation amplitudes asymmetry \( A \) using Eq. \( 8 \), we need to know the bias of the quasars. If one assumes a cosmological model, one may obtain this by fitting to the correlation function. Here we use the WMAP5+BAO cosmology, based on combining the WMAP 5-year power spectrum \([64]\) with the SDSS+ 2dF baryon acoustic oscillation (BAO) constraint \([66]\); this combination yields \( \theta = 0.807 \pm 0.027 [27] \).

If one has a measured correlation length \( r_{0} \) and an assumed cosmology, the bias can be obtained by the formula \( b = [\theta_{m}(r_{0})]^{1-2} \), where \( \theta_{m} \) is the matter correlation function. We have used the linear correlation function using the Eisenstein & Hu transfer function \([66]\) since in the regime of interest the nonlinear corrections as estimated by the Smith et al. \([67]\) prescription are \( < 1\% \), i.e., negligible. The correlation lengths that Shen et al. \([57]\) measured from the \( \text{good}^{n} \) fields are \( 1791 \pm 150 \text{h}^{-1} \text{Mpc} \) (2.9 \( z < 3.5 \)) and \( 2522 \pm 250 \text{h}^{-1} \text{Mpc} \) (3.5 \( z < 3.5 \)). These correlation lengths in ply are \( b = 0.7 \) (2.9 \( z = 3.2 \)) and \( b = 1.7 \) (3.5 \( z = 4.4 \)), where the uncertainty is simply propagated from \( r_{0} \). There is some additional uncertainty in these numbers from nonlinear biasing, from the cosmological parameters, and because the correlation length does not appear to be constant with redshift. We note that the one-half term in the correlation function cannot contaminate these measurements because Shen et al. only projected separations \( r_{p} > 4 \text{h}^{-1} \text{Mpc} \). Integrating over the redshift bin assuming a constant correlation length \( r_{0} \), we turn Eq. \( 8 \) into:

\[
d = (5.8 \pm 0.5)_{\text{p}} \text{ low } z \text{ slice } \quad (18)
\]

Using the central value of the conversion from the observed quasar dipole into \( p \), and the conservative (good + dust + marginalization) dipole estimates, we obtain \( 10^{2}p = (0.7 \pm 0.1; 0.8; 0.7; 0.9; 0.2; 1.9; 0.9) \) for the low-\( z \) slice and \( (0.7; \text{p}; 1.9; 0.9) \) for the high-\( z \) slice. Combining the two results with the usual weighting by their inverse-covariance matrix gives:

\[
10^{2}p = (0.73; 0.81; 1.01); \quad (19)
\]
With covariance:

\[
\begin{bmatrix}
0 & 0.306 & 0.225 & 0.122 \\
0.306 & 1 & 0.225 & 0.122 \\
0.225 & 0.122 & 0.225 & 0.97 \\
0.122 & 0.97 & 0.225 & 1
\end{bmatrix}
\]

(20)

In the optimal determination of the central value (Eq. 19) the low-redshift slice receives 30% of the weight and the high-redshift slice receives 70%, i.e.

\[
p = w_{lo} p_{lo} + w_{hi} p_{hi}
\]

(21)

with \( w_{lo} = 0.30 \) and \( w_{hi} = 0.70 \).

The difference between the inferred dipoles from the two samples is \( p_{lo} - p_{hi} = (0.1;0.1;0.1) \ 10^2 \); based on the covariance matrix for the difference, the \( \chi^2 \) is 3.03 (3 degrees of freedom; \( P = 0.39 \)) so we conclude the dipoles measured from the two redshift slices are consistent. There is no detection of any global dipole (\( \chi^2 = 2.80; P = 0.42 \)).

If one xes \( \beta \) to be in the specific direction (\( \beta = (225; 27) \)) estimated by Erskine et al. [19], then the magnitude \( A \) of \( p \) is found to be \( A = 0.18 \ 0.44 \), i.e. \( 0.0105 < A < 0.0070 \) at 95% confidence (\( 0.0132 < A < 0.0097 \) at 99%). A direction-independent upper limit can be set by a Bayesian analysis analogous to Erskine et al.; by placing a uniform prior on the magnitude \( A \) and direction \( \beta \), we can construct a marginalized likelihood function for \( A \):

\[
L(A) = \frac{1}{2} \exp \left( \frac{1}{2} (p - p_{\text{best}}) \text{Cov} \ (p - p_{\text{best}}) d^3 \beta \right)
\]

(22)

where \( p = A \beta \). We nd that 95% of the Bayesian posterior distribution is at \( A < 0.019 \) and 99% at \( A < 0.026 \).

In reality the above computations should take into account the uncertainty in the estimator response, Eq. 19, which derives from the uncertainty in the quasar bias. In particular it is possible to circumvent the above limits on \( p \) if the quasar bias is smaller than central values. For our chosen weights, Eq. 21, the response of our estimator is:

\[
P_{\text{estimated}} = (1.10 \ 0.99) P_{\text{actual}}
\]

(23)

i.e. there is a 9% (1) calibration uncertainty. We can include this uncertainty in a Bayesian analysis by incorporating a calibration factor with a prior at 1.10 0.99. For the fixed-direction case (i.e. where \( \beta \) is required to point in the Erskine et al. direction), one may determine a marginalized likelihood function for \( A \):

\[
L_{\text{marg}}(A) = \frac{1}{2} \exp \left( \frac{1}{2} (A + 0.018)^2 + 2(0.0044)^2 \right) e^{(1)^2 - 2(0.009)^2} \ d
\]

(24)

This gives \( 0.0108 < A < 0.0071 \) (95%) or \( 0.0138 < A < 0.0100 \) (99%). For the direction-independent case, we find that 95% of the Bayesian posterior distribution is at \( A < 0.020 \) and 99% is at \( A < 0.027 \). These are negligible changes from the un-marginalized case.

Since \( A \) is the magnitude of \( p \), in our direction-independent constraint \( \beta \) is required to be non-negative. In the fixed-direction constraint where \( \beta \) is fixed to the Erskine et al. direction, we allow for the possibility of negative \( A \), i.e. a dipole opposite to that seen in the CMB.
Here we have also repeated the above analysis for the \"all\" quasars. In this case, the correlation length measured by Shen et al \cite{57} is shorter, so the biases are less: $b = 8.0$ at $z = 3.2$ and $b = 13.5$ at $z = 4.0$. The dipole response is now

$$\text{d} = \begin{pmatrix} 5.1 \\ 10.0 \end{pmatrix} \text{p low z slice} \quad \begin{pmatrix} 0.7 \\ 1.3 \end{pmatrix} \text{p high z slice}.$$

The best-fit dipole and its covariance are:

$$10^2 \text{p} = (0.80; 0.87; 0.52)$$

and

$$10^4 \text{cov}_{(\theta)} = \begin{pmatrix} 0.351 & 0.259 & 0.141 \\ 0.259 & 0.571 & 0.261A \\ 0.141 & 0.261 & 0.543 \end{pmatrix}.$$}

The weights in this case are $w_\text{lo} z = 0.80$ and $w_\text{hi} z = 0.70$. Again the low- and high-z slices are consistent ($^2 = 3.11, P = 0.37$). There is also no detection of $p$; the $^2$ for zero dipole is $1.34 (P = 0.72)$. The calibration uncertainty is now $10\%$. After marginalizing over this, the xed-direction constraint on $A$ is $0.0073 < A < 0.0120 (95\%)$ or $0.0105 < A < 0.0153 (99\%)$, and the direction-independent constraint is $A < 0.017 (95\%)$ or $A < 0.025 (99\%)$.

3.6. Scale of constraint

Up until now we have assumed that the dipole anisotropy $\theta$ is scale-invariant. However, in stationary models usually predict slight deviations from scale invariance because as one approaches the end of inflation each e-fold is slightly different from the previous one. In order to constrain such models, we need to know the effective scale at which the quasars constrain $\theta$. Since the fluctuation amplitude is typically a smoothly varying function of the number of e-folds or equivalently of $\ln k$, only a rough estimate of $k_e$ is required.

We now obtain an estimate of the scale probed by the quasars, i.e., at what scale $k_e$ we have actually constrained the large-scale gradient of the fluctuation amplitude. The abundance of very massive haloes (i.e., well above the nonlinear mass) is roughly determined by the top-hat variance ($R$), where $M = 4 M_\odot R^3 = 3$ is the halo mass, $m_\odot$ is the present-day matter density, and $R$ is the comoving radius of the top-hat sphere. This is:

$$V_R^2 = \frac{2(kW)^2(kR)}{2(kW)^2(kR)dlnk};$$

where the window function is $W((x)) = 3/2(x) = x$. Differentiating gives

$$\ln R = \frac{2(kW)^2(kR)}{2(kW)^2(kR)dlnk};$$

This can be approximated as

$$\ln R = \ln (k_e),$$

where:

$$\ln k_e = \frac{2(kW)^2(kR)dlnk}{2(kW)^2(kR)dlnk};$$

For the quasars, the minimum mass (which for a steep mass function can be taken as a typical mass) is $M = 10^{12} M_\odot$ \cite{57}, which gives $k_e = (1.3 \times 10^5) M_\odot$.
This range spans only 0.3 e-folds and in what follows we will thus take the central value, \( k_e = 1.5h \text{Mpc}^{-1} \).

One can make a similar estimate for the Eröken et al. \[10]\; we nd in Appendix A that \( k_e = 0.033h \text{Mpc}^{-1} \). The Eröken et al. constraint and our constraint are thus separated by 6.1 e-folds. This strongly constrains in ationary explanations for the power asymmetry: the asymmetry amplitude \( A \) must decrease by a factor of at least a few ( \( 7\% \) to \( 1\% \)) during only 6.1 e-folds of expansion. This contrasts with the usual expectation from in ationary models of nearly scale-invariant spectra. One could imagine features in the in ationary potential that strongly break scale invariance; however, there is no motivation to place such features in precisely this range of \( \ln k \), and moreover such a model would have to avoid “breaking” the successes of standard in ation in predicting the CMB acoustic peak regime and large-scale galaxy clustering. A detailed study of such constraints is presented in a companion paper \[69]\.

4. Discussion

One of the intriguing products of the WMAP mission was the detection of large-scale anom alies in the CMB. If these anomalies are “real” (as opposed to statistical uctuations or systematics) then their implications are revolutionary. The anomalies are thus in need of confirmation, both by future CMB data that could detect them at higher signal-to-noise ratio (e.g. Planck) and just as importantly by independent probes of the same underlying physics. In particular, the dipolar asymmetry in the CMB power spectrum reported by Eröken et al. \[10]\; if interpreted as a spatial variation of the amplitude of primordial uctuations, makes predictions not just for the CMB but also for large-scale structure: if there is truly a large-scale gradient \( r\) across the Universe, then there should be a corresponding gradient in the number density of highly biased objects. We have searched for such a gradient using the SDSS \( z \geq 2.9\) quasars and found a null result. We nd that the dipole \( p = r_{\text{max}} \ln \theta \) is no more than 0.027 (99\% posterior probability), i.e. any smooth gradient in the amplitude of uctuations is no more than 2.7 percent per present-day horizon radius. Tighter results are obtained if one forces the gradient to be in the same direction as that reported by Eröken et al. \[10]\.

This result rules out the simple curvaton-gradient model \[20]\; in which the power asymmetry in the CMB comes from a spatial gradient in the curvaton eld of a two-eld in ation model. Such a model requires \( 0:11 \) to reproduce the reported 1\% variation in the CMB amplitude across the sky \[13]\; this does not necessarily contradict the Eröken et al. \[10]\; result: there may be more complicated models with a scale-dependent gradient in small-scale power, i.e. where the spatial gradient of the local \( \ln P(k) \) depends on \( k \). Such models, including some that predict much smaller dipoles in the quasar distribution and the degree-scale CMB uctuation amplitudes, are explored in the companion paper by Eröken et al. \[69]\.

Acknowledgments

Appendix A. Effective scale of CMB power asymmetry

Eriksen et al. [10] measured a dipole asymmetry in the CMB power spectrum in the range of multipoles $l < l_{\text{max}}$ of $40$. The upper limit $l_{\text{max}}$ was set by the requirement to be oversampled on the HEALPix resolution $4 (N_{\text{side}} = 16)$ pixelization scheme [68]. Our goal here is to estimate the effective wavenumber of the Eriksen et al. measurement.

In the Sachs-Wolfe regime, and neglecting the small contribution from the integrated Sachs-Wolfe effect, the temperature perturbation is given by $(\hat{\eta}) = (\eta_{\text{d}}) = 5$ where $\eta$ is the primordial curvature perturbation. Therefore, the CMB power spectrum at multipoles $l$ is obtained by:

$$ C_\ell = \frac{4}{25} \left( x \right)^2 \left( x^2 - 1 \right)^{1/2} \cos^2 \left( x \right) \delta^2 \left( k \right) \delta \ln k; \quad (A.1) $$

where $\delta^2 \left( k \right)$ is the primordial curvature power spectrum. [See, e.g., Eqs. (5.27) and (5.39) of Ref. [70].] For smooth power spectra and $l > 1$, we can use the Wenzel-Kramers-Brillouin approximation for the spherical Bessel function,

$$ j_l (x) \approx x^{1/2} \left( x^2 - 1 \right)^{1/4} \cos \left( x \right) \quad (A.2) $$

for $x > 1$, where $(x)$ is a rapidly oscillating phase. (For $x < 1$, the spherical Bessel function goes rapidly to zero.) With this approximation, and taking $\cos^2 \left( x \right)$ into account, $C$, simplifies to:

$$ C_\ell = \frac{2}{25} \left( x \right)^2 \left( y^2 - 1 \right)^{1/2} \delta^2 \left( k \right) \delta \ln k; \quad (A.3) $$

where $y = x' = kr_{\text{los}}$. The fractional dipole asymmetry in C. of $C_\ell$ is given by:

$$ l \ln C_\ell = \frac{\int_a^b y^2 \left( y^2 - 1 \right)^{1/2} \delta^2 \left( k \right) \delta \ln k}{\int_a^b y^2 \left( y^2 - 1 \right)^{1/2} \delta^2 \left( k \right) \delta \ln k}; \quad (A.4) $$
This equation can be simplified for the case of a near scale-invariant reference spectrum, \( \dot{2}(k) = \text{constant} \):

\[
\ln C_{\ell} = \int_{-1}^{1} \frac{R_{\ell}^i}{y^2 - 1} (y^2 - 1)^{1/2} \ln ^2(\ell) dy:
\]

(A.5)

The integral in the denominator evaluates to 1 (with the substitution \( y = \sec \theta \)).

In order to make further progress, we assume that \( \ln ^2(\ell) \) varies smoothly with \( \ln k \), as typical during linear models, i.e. we assume:

\[
\ln ^2(\ell) = B_1 + B_2 (\ln(1 + k)):
\]

(A.6)

Only the \( y \) part of the \( \ln \) integral is nontrivial,

\[
\ln C_{\ell} = B_1 + B_2 \ln ' + B_2 \ln \ln \ln y:
\]

(A.7)

The integral over \( y \) can be solved by the substitution \( y = (1 + x^2)^{1/2} \), which turns it into \( \frac{1}{2} \int_{0}^{1} \ln (1 + x^2) dx \). The \( \ln \) functions are then integrated by parts.

The the Eriksen et al. [10] dipole asymmetry measurement is a single amplitude for the power asymmetry across their entire range of \( \ell \). In the limit where all multipoles up to \( \ell_{\text{max}} \) are signal-dominated and those above \( \ell_{\text{max}} \) are noise-dominated, the Eriksen et al. asymmetry parameter \( A \) will receive equal weight from all multipoles, i.e.

\[
A = \frac{1}{2} \int_{0}^{1} \ln C_{\ell_{\text{max}}} \frac{1}{2} [B_1 + B_2 \ln ' + B_2 (1 + \ln 2)]:
\]

(A.8)

(The factor of 1/2 comes from the fact that Eriksen et al. measured an amplitude asymmetry rather than a power asymmetry.) Since the number of multipoles in any region of the sky and any \( \ell \) range is proportional to \( \ell \), we have, for \( \ell_{\text{max}} = 1 \),

\[
\ln ' \ell_{\text{max}} = \frac{R_{\ell_{\text{max}}}^i}{B_1 + B_2 \ln ' + B_2 (1 + \ln 2)}:
\]

(A.9)

(The integral in the numerator is evaluated using repeated integration by parts.) Thus:

\[
A = \frac{1}{2} \int_{0}^{1} \ln C_{\ell_{\text{max}}} \frac{1}{2} [B_1 + B_2 \ln ' + \frac{1}{2} \ln 2] :
\]

(A.10)

This is the same as the amplitude asymmetry \( \frac{1}{2} \ln ^2(k_e) \) at the effective scale:

\[
k_e = \frac{e^{1/2} \ell_{\text{max}}}{2 \ell_{\text{max}}}:
\]

(A.11)

where \( e = 2.718 \ldots \) is the base of the natural logarithm.

For the specific case of Eriksen et al., \( \ell_{\text{max}} = 150 \), \( 10\; h^{-1}\; \text{Mpc} \) and \( \ell_{\text{max}} = 40 \), so \( k_e = 0.0033\; h\; \text{Mpc}^{-1} \). Similarly, for Hoftuft et al. [12], \( k_e = 0.0053\; h\; \text{Mpc}^{-1} \) (\( \ell_{\text{max}} = 64 \)) or \( k_e = 0.0066\; h\; \text{Mpc}^{-1} \) (\( \ell_{\text{max}} = 80 \)).
