²Herschel Space Observatory Mission Scientist

Abstract

The mid- and far-IR spectral ranges are critical windows to characterize the physical and chemical processes that transform the interstellar gas and dust into stars and planets. Sources in the earliest phases of star formation and in the latest stages of stellar evolution release most of their energy at these wavelengths. Besides, the mid- and far-IR ranges provide key spectral diagnostics of the gas chemistry (water, light hydrocarbons, organic species ...), of the prevailing physical conditions (H₂, atomic and molecular structures ...), and of the dust medium and ice composition that cannot be observed from ground-based telescopes.

With the launch of JAXA’s SPIKA telescope, uninterrupted studies in these mid- and far-IR windows will be possible since ESA’s Infrared Space Observatory (1995). In particular, SAFARI will provide full access to the 34-210 μm waveband through several detector arrays and enable observing m cores (from broadband photon ety to m edium reso- lution spectroscopy with R = 3,000 at 63 μm), and reaching very high line sensitivities (10⁻¹⁵ W m⁻² S⁻¹μm⁻¹) within a large FOV (2⁰ × 2⁰). Compared to previous far-IR instruments (ISO /LWS, Akari/FIS, Spitzer/MIPS and Herschel/PACS), SAFARI will provide a superior way to obtain fully-sampled spectra in ages and continuous SEDs of very faint and extended ISM sources in a wavelength domain not accessible to JWST or ALMA. The much increased sensitivity of SPIKA will allow us to step forward and reveal not only the chemical composition in the local ISM, but also in the extragalactic ISM routinely.

Key words: astrochemistry, ISM, IRS, clouds, line formation, M issions: SPIKA

1. Introduction

Due to the atm ospheric opacity, the mid- and far-infrared domain has been the latest spectral windows used in astrochemistry. The potential of opening a new spectral wavelength range for molecular spectroscopy began to be fully exploited by ESA’s Infrared Space Observatory, ISO (Kessler et al. 1996), and has been successfully continued by NASA’s Spitzer (Werner et al. 2004) and JAXA’s Akari (Murakami et al. 2007), and it will further advance with ESA’s Herschel Space Observatory (Pilbratt et al. 2009).

Before ISO, the mid- and far-IR spectra of the most relevant interstellar (ISM) and circumstellar (CSM) sources were unknown. In particular, most gas-phase species emitting in the mid- and far-IR were unidentified. Nowadays we know that the spectral features that can be detected in this domain are essential to study the physical and chemical content of a broad range of astronomical environments. Such diagnostics include atomic and molecular structure lines, PAG bands, H₂ lines, light hydrocarbons, and many non-polar molecules that can be detected with ground-based telescopes (e.g., PdBI, SMA or ALMA and SKA in the future). Besides, the mid- and far-IR will provide access to a great variety of ices and mineral features that help us to understand the life cycle of cosmic dust.

In this short contribution we argue why a very sensitive space telescope covering the full mid- and far-IR range can drastically contribute to probe our understanding of the chemical composition in the Universe. We also review some representative examples of previous mid- and far-IR observations towards very bright ISM and CSM sources in the Milky Way. These spectra reveal unique ones of the diagnostic power of this domain, and are archetypes of what much more sensitive space telescopes (SPIKA!) will routinely observe in much fainter regions of the sky, and that are beyond the sensitivity capabilities of Herschel. The combination of dust grains and PAHs to the mid- and far-IR spectrum of different environments is well covered by other papers in these proceedings. Here we shall put more emphasis on gas phase molecular spectroscopy. More detailed reviews can be found in e.g., van Dishoeck (2004) or Cernicharo & Crovisier (2005).

2. Why another mid- and far-IR space telescope?

The life cycle of interstellar gas and dust has been traditionally studied through line absorption observations in the UV and visible domain (e.g., the di-use and translucent ISM) and through sub-mm, mm, and cm observations with ground-based radio telescopes (usually by detecting emission lines). Due to the atmospheric opacity and because of the nature of IR detectors, observations over the entire mid- and far-IR bands require space telescopes and cryogenic instrumentation (down to a few mK). Both require extreme precision and technical and financial challenges, as well as notable international collaboration. All of them can be better justified if...
1) Science drivers are exciting and unique (hard to achieve with other instrumentations). 2) Instruments provide outstanding scientific results (with great impact in the field).

In (gas phase) astrochemistry there are three particular areas that are only accessible in the mid- and far-IR:

- Fine structure lines from key gas reservoirs such as $\text{[FeII]}_{62}, \text{[SiII]}_{15}, \text{[CII]}_{158}$ m ($E_i < 13.6\text{eV}$) that are critical diagnostics of the neutral gas component of the ISM and are often the most important cooling lines. On the other hand, fine structure lines of ions with $E_i > 13.6\text{eV}$ ($\text{[OIII]}_{50}, \text{[NIII]}_{85}$ m, ...) trace the ionized gas component (e.g., H II regions: electron densities, ionization radiation strength, etc.). All these lines are usually bright and are not affected by extinction problems as they are at shorter wavelengths (visible and near-IR).

- Light molecules that have their pure rotational transitions in this range: e.g., $H_2$, water vapor, $OH$, HD, $H_2D^+$ and many other hydrides. Together with the above atoms and molecules, their spectral signature allows one to penetrate heavily obscured regions like star forming regions or the ISM in galactic nuclei, and provide means to derive the physical conditions (densities, temperatures, UV fields) and the chemical composition in harsh environments (e.g., UV irradiated regions, XDRs, shocked-regions, etc.). Heavier species (CO, HCN, ...) have their high energy transitions in this domain (their $J=J$ transitions) and trace even higher temperatures and density phenomena (e.g., strongly shocked-regions such as SN remnants, the inner circumstellar shells around evolved stars, etc.).

- Organic chemistry: symmetric small molecules (i.e., all species lacking a permanent electric dipole) do not have pure rotational lines (i.e., to be observed from radiotelescopes) but do show vibration-rotation transitions in the mid- and far-IR (stretching and bending modes). Very relevant and abundant species of this kind are, for example, acetylene ($C_2H_2$), methane (CH$_4$), carbon dioxide (CO$_2$), benzene (C$_6$H$_6$), many different pure carbon chains (C$_n$), and of course, the ubiquitous polycyclic aromatic hydrocarbons (PAHs).

3. The interstellar gas and dust life-cycle

The rest of the four Cosmic Vision (CV) Themes is proposed by ESA: What are the conditions for planet formation and the emergence of life? "calls for a mission able to investigate star-formation areas and protostars..." and investigate the conditions for star formation and evolution". As stated in the CV objectives, we still lack a comprehensive theory explaining why and how stars form from interstellar matter and, apparently quite often, planetary systems with them. SPIRA instruments will make decisive contributions to the study of the physical and chemical processes that transform the gas and dust into stars and planets", or in other words, it will follow the life-cycle of matter from the formation of dust grains in circumstellar shells to its incorporation to planet forming disks, some of them maybe similar to what our own Solar System looked like at the time of its formation (see the gas and dust life-cycle diagram in Figure 1).
**SPICA** observations will allow us to significantly improve our knowledge of many areas related with planetary formation and evolution (see detailed contributions in these proceedings). As a unique complement, **SPICA** will decisively contribute to unveil the initial conditions for star formation (a mission able to unravel the birth of stars and planets by peering into the highly obscured cocoons where they form) and in the processes associated with stellar death (e.g., supermassive black hole flares). The chemical enrichment and mixing of the ISM gas and dust will be a subsequence of star formation.

The processes of molecular cloud formation, star formation and star death are poorly understood because of the large amount of dust obscuring them, as are the circumstellar envelopes (CSE) of molecular gas and dust created at the end of Sun-like stars’ lives. Since this dust becomes “transparent” at far-IR wavelengths, this spectral window provides the natural way to penetrate these envelopes. By observing in the mid- and far-IR, **SPICA** will provide and unprecedented window into key aspects of the gas and dust lifecycle: from its formation in evolved stars, its evolution in the ISM, its processing in supernova-generated shock waves and near massive stars (winds, H II regions, etc.), to its nucleation into star forming cores, protostars, protoplanetary disks and eventually planets.

Very important gas-phase species that cannot be observed from the ground have their spectral signatures in the observable range of **SPICA**. Such spectral diagnostics provide clues on the elemental abundances of key elements (C, O, D, Si, ...) and they also provide deep insights into the gas/dust chemical interplay: deuteration enrichment, ice formation, grain growth, evaporation, photodesorption or metal depletion on grains (e.g., Oka et al. 2008).

4. Local and extragalactic ISM with **SPICA**

A major fraction of the interactions that transform the gas and dust into dense molecular clouds and stars, takes place over very large scale regions, several arcmin in size (e.g., diffuse ISM clouds, cirrus, high latitude clouds, star forming regions, circumstellar shells, supernova remnants, etc.) that are too faint to be mapped entirely by Herschel in spectroscopy mode, or too extended to be mapped with ground-based interferometers. In this context, the niche of **SPICA**/SAFARI is to provide far-IR spectroscopic maps of many key spectral diagnostics simultaneously of the regions that are too obscured for JWST to examine or too warm/extended to be easily traced with ALMA in the mid/millimeter domain.

**SPICA** instrument teams have the appropriate combination of spatial and spectral resolution together with high sensitivity and large field-of-view (FOV) to follow the evolution of interstellar matter over very large spatial scales (e.g., by taking full SEDs and spectra of distant star forming regions), study meaningful samples of compact sources (e.g., hundreds of protostars, distant evolved stars and disks around all types of stars and ages) and out to large distances (inaccessible to previous telescopes).

In the following we just list several fields where we anticipate SAFARI can play a unique role (difficult to achieve with other telescopes):

- Spectro-imager of the ISM in nearby galaxies.
- Chemical complexity beyond our galaxy.
- Continuous SEDs of young stellar objects.
- High-mass star formation in distant SF regions.
- Evolved stars and interaction with ISM.
- Supernova remnants (dust formation and processing?).
- Molecular cloud formation.
- The first identification of PAH molecules in space.

Thanks to its much improved sensitivity, **SPICA** will extend our knowledge of the physics and chemistry of the ISM matter in our galaxy to similar detailed studies of the ISM in nearby, spatially resolved galaxies (see e.g., Gonzalez-Afonso et al. 2004; Olofsson et al. 2005).

4.1. What will not be done by Herschel & JWST?

The successful launch of ESA’s Herschel Space Observatory in May 2009 (the biggest IR telescope ever launched) suggests that Herschel will be a major breakthrough for far-IR and submm astronomy. At the time of writing, com misioning has been declared successful and the instrument teams are now in the performance and verification phase. However, Herschel has several constraints and there will be many critical areas of the ISM and the CS in research that will not be covered due to limited sensitivity, wavelength coverage or spectral resolution:

- **Herschel** observes the 55 to 672 m waveband so it does not access the mid-IR domain where most physical and chemical studies can be carried out. Similarly, it cannot observe the mid-IR emission of PAHs and most organic molecules or the high excitation transitions (high-J) of many species. **SPICA**, however, will cover the full 5 to 210 m waveband (baseline).
- Herschel is a warm telescope which greatly limits its sensitivity and thus mapping speed to obtain spectroscopic ages of very extended/distant ISM sources. **SAFARI** will cover the critical 34-210 m that is not accessible to JWST or ALMA with a factor 200 (in photometry) and 20 (in spectroscopy) better sensitivity than Herschel/PACS, and with a wider instantaneous FOV (i.e., 2° 2°, a factor 6.5 larger).
- JWST/MIRI (> 2014) will operate in the mid-IR (5-28 m band), so it does not cover the far-IR. **MIRI** will provide imaging and medium-resolution spectroscopy (R 3000) over a small FOV (a few arcsec). **SPICA**’s mid-IR can cover large FOVs and out to an order of magnitude higher spectral resolution (R 30,000) in selected mid-IR wavebands.
Despite its modest monolithic mirror size (D = 3.5m, similar to Herschel) the SPIRA telescope will be actively cooled down to 4.5 K (compared to 45 K through passive cooling for JWST), and thus will reach similar sensitivities than JWST/MIRI in the mid-IR (around 1 Jy) but with a much increased wavelength range (including the far-IR), wider FOV and increased observing efficiency due to the use of multiple detector arrays.

4.2. What will not be done by ALMA?

The Atacama Large Millimeter Array (ALMA) will be fully operational the next decade. With its extremely high angular resolution and huge collecting area, ALMA will be a major revolution in any eddies of the cold and molecular Universe. However, ALMA observes at wavelengths longer than 315 μm (< 950 GHz) and for practical reasons (it is a very long-baseline interferometer) it is not designed to carry out extensive surveys of very large regions of the sky. In addition, there are critical spectral diagnostics (at their rest frame wavelengths) that are not accessible to ALMA:

- The study of the oxygen chemistry will be limited to observations of CO, HCO⁺ and other trace species, but it will not observe the emission of the major oxygen reservoirs (e.g., atomic oxygen, water ice, CO₂ or the thallium line emission of water vapor).
- The most important atomic and ionic structure lines are outside the coverage of ALMA, which will limit the determination of the physical conditions (temperatures, densities and radiation fields) and the study of the energy balance (heating and cooling) in PDRs, XDRs, and shock-like environments.
- ALMA can only detect the mm/submm dust continuum emission but it cannot observe the specific grain and ice spectral features that are needed to determine the dust composition and its formation history along the life-cycle of interstellar matter.
- ALMA will not even touch several aspects of the chemical complexity in the Universe. In particular, it will not observe molecules without permanent electric dipole or the mid-IR emission of PAHs, thus missing a significant fraction of the organic chemistry in space.

Note, however, that the above IR spectral diagnostics become available to ALMA in highly-redshifted extragalactic sources. In particular, ALMA will detect the restframe mid- and far-IR spectrum of sources at redshifts
of z > \frac{315}{\text{rest}(z)} \) 1. For example, z > 4 for the [O I]63 m line and z > 10 for the H$_2$ 0-0 S(0) line at rest = 28 m.

5. Examples of mid-IR and far-IR spectroscopy

We now review some interesting results of previous mid- and far-IR observations towards Sgr B2 and Orion KL high-mass star forming regions (SFRs). Sgr B2 (8.5 kpc) and Orion KL (~450 pc) can be considered as two of the most remakable giant molecular clouds for astrochemistry studies. They are also very appropriate sources to construct a template for more distant (e.g., fainter) and unresolved regions (e.g., extragalactic). The cores of both SFRs are the most prolific sites of molecular line emission/absorption in the Galaxy (in terms of density and intensity/absorption depth of lines). Due to the large column density of warm molecular material (Sgr B2) or due to its proximity (Orion), both complexes are among the brightest far-IR sources of the sky. For these reasons, Sgr B2 and Orion KL were fully surveyed between 2.4 and 197 μm by ISO’s SW S and LW S spectrometers. The resulting spectra are an unique example of the diagnostic power of this domain and arc archetypes of what SPICA could routinely observe in such fainter sources (protoplanetary disks, outer Solar Systems, etc.).

5.1. The mid- and far-IR spectrum of a SFR

The far-IR spectrum (47-196 μm) of Sgr B2 (see Figure 2; Gobbo et al. 2004; Polychroni et al. 2007 and references therein) contains: (i) The peak of the thermal emission from dust (a blackbody at 30 K roughly peaks at 100 μm); (ii) Atomic and molecular emission lines of the warm gas, and excellent discriminants of the PDR, H II and shock emission (e.g., CO, [C II], [N II], [S II], and [O III]); (iii) Rotational lines from key heavy molecules (H$_2$O, OH, H$_2$O$^+$, CH$_2$, CH$\equiv$CH, NH$_3$, NH$\equiv$CH, NH, HF, HD, H$_2$D$^+$) and ro-vibrational lines from abundant nonpolar molecules (C$_2$H). These species provide unique information on the prevailing physical conditions and on the basic O, C, N, and D chemistry. Most of the molecular lines appear in absorption whereas atomic and ionic lines appear in emission (except for absorption in the [O I]63 and [C II]158 μm lines). In particular, [O I]63 and [C II]158 μm absorption lines provide clues regarding several peculiarities observed in some extragalactic spectra at lower resolution (e.g., the [C II]/far-IR de cit). The main gas component traced by far-IR observations is the warm, low density envelope of Sgr B2 (Γ$_k$ ~ 300 K; n(H$_2$) ~ 10$^4$ cm$^{-3}$). Given the low densities in this component, no high-J CO line was detected at ISO’s sensitivity. This situation may apply to other warm regions observed in the far-IR. The warm, low density gas is particularly difficult to trace in the millimeter domain where such molecular transitions are not observed. Finally, because of its location in the Galactic Center, all ground state lines towards Sgr B2 show a broad absorption profile due to foreground absorption produced by interstellar dust clouds in the line of sight.

On the other hand, the far-IR spectrum of Orion KL (Leroy et al. 2006 and references therein) is dominated by emission lines from molecular (H$_2$O, high-J CO, OH) and atomic species. Interestingly enough, H$_2$O and OH line profiles show a common behavior evolving from pure absorption, P Cygni type, to pure emission, depending on the transition wavelength, $E_{\text{up}}$, and line opacity. These lines arise from Orion outer (c) and associated shocked regions. Without resolving these lines, low resolution spectra of similar regions may be interpreted via the prevailing dynamical and physical conditions. Given the high densities and tens of parsecs of Orion’s shocked gas, CO pure rotational emission up to J = 39 has been detected (with an upper energy level of $E_{\text{up}}$ ~ 4,000 K (!)).

Figure 3. Mid-infrared spectrum of Orion Peak 1 shock obtained in the ISO/SW S grating scan observing mode (R ~ 2,000). Some of the strongest lines and bands are labeled. The continuum levels of the individual bands, which di er due to aperture changes, were adjusted to make the spectra appear continuous. Adopted from Rosenthal et al. (2000).

Fig. 3 shows the ISO/SW S (2.4-45 μm) spectrum of the brightest m.i. (IR: H$_2$ emission peak of the Orion out ow (see Rosenthal et al. 2000). This is one of the most spectacular shocked regions in the galaxy. 56 Hz rovibrational (up to $E_{\text{up}}$ ~ 14,000 K) and pure rotational lines from the Hz 0-0 S(1) to 0-0 S(25) lines are detected. The spectrum also shows a number of PAH bands, H I recom bination lines, ro-vibrational lines of CO (-1-0; 4.7 μm) and Hz (2-1-0; 6.5 μm) and many ionized structure lines (He II, Fe II, Ne II, O I, Ne III, Ne IV, Ne V, Si II, Si III, Si IV, Si V, Fe II, Fe III) and [Ne III, [Ne II]] and [Ne I]$\lambda$ 12.25 μm), most of them con ing from the foreground H ii region and its bounding PDR. Van Dishoeck et al. (1998) also observed
the Orion-IRc2 position with the same spectrometer. In addition, several broadband features associated to silicate grains and H$_2$O (ice and CO$_2$ (ice were detected along the line of sight to the strong mid-IR continuum of IRc2.

Figure 4. M id-IR spectrum of CRL 618 at selected wavelengths. The thin line in each panel corresponds to the model results discussed by Cerricharo et al. (2001a). The feature at 7.27 m corresponds to the symmetric bending mode of CH$_3$. The broad range of absorption bands produced by wagging and twisting modes of CH$_2$ is indicated by the horizontal line (Silverstein & W elster 1998). Figure from Cerricharo et al. (2001a).

5.2. M id-IR: Chemical complexity

M id-IR spectroscopy (vibrational spectroscopy in particular) is a powerful tool to reveal the chemical complexity in the Universe. An remarkable example is the organic composition of the circumstellar envelopes around evolved stars. Many organic species lack rotational spectra to be observed from Radiotelescopes (e.g., polycyclic aromatic chains; see Figure 2). Benzene, the most basic aromatic unit, has been detected outside the Solar System only towards CRL 618 carbon-rich protoplanetary nebulae, PPNe (see Figure 5; Cerricharo et al. 2001b) where the physical conditions in the inner CSE (shocks and UV photons) seem to drive the polymerization of acetylene and the formation of benzene. This means that carbon-rich PPNe may be the prototype organic chemistry factories in space and much can be learned about the gas/dust chemistry in interplay (e.g., the formation of larger aromatic species or PAHs). SPICA’s very high-resolution mid-IR spectra will have the required sensitivity to study the organic content and reveal the degree of chemical complexity, not only towards the brightest sources in the sky, but everywhere in the Milky Way and in nearby galaxies.

Figure 5. M id-IR spectrum of CRL 618 around 15 m. The infrared bands of the polynyes (C$_4$H$_2$, C$_6$H$_2$), benzene, and cyanopolyynes are indicated by arrows. The thin line corresponds to the synthetic spectrum for C$_4$H$_2$, HCN, C$_6$H$_2$, C$_4$H$_2$, HC$_3$N, and HC$_5$N. All the narrow features to the right and left of the Q-branches of C$_4$H$_2$ and HCN correspond to the individual rovibrational lines of the P- and R-branches of these same two species. Figure from Cerricharo et al. (2001b).

6. Conclusions

The mid- and far-IR domains provides key spectral diagnostics of the gas phase chemistry (e.g., water vapor, H$_2$, PAHs, organic species), of the prevailing physical conditions (atomic and ionic structure lines), and of the dust model/ice capotition that can not be observed at other wavelengths. Thanks to SPICA, uninterrupted studies in the critical 5-210 m range will be possible since the launch of ISO with orders of magnitude higher sensitivity and resolutions. Therefore, SPICA observations will revolutionize the study of the life-cycle of interstellar matter in nearby galaxies the same way ISO revolutionized the study of the ISM in the Milky Way in the late 90’s.

Acknowledgements

JRG thanks the European and Japanese SPICA science teams for fruitful discussions and different contributions to develop the gas and dust life-cycle case. We warmly thank Marcelino Agundez for letting use his life-cycle figure. JRG is supported by a Ramón y Cajal research contract.
