(Date: August 5, 2013)

A general method, which we call the potential $S$-matrix pole method, is developed for obtaining the $S$-matrix pole parameters for bound, virtual and resonant states based on numerical solutions of the Schrödinger equation. This method is well-known for bound states. In this work we generalize it for resonant and virtual states, although the corresponding solutions increase exponentially when $r > 1$. Concrete calculations are performed for the $1^1$ ground and the $0^-$ first excited states of $^{14}$N, the resonance $^{15}$F states ($1=2', 5=2'$), low-lying states of $^{11}$Be and $^{13}$N, and the subthreshold resonances in the proton-proton system. We also demonstrate that in the case the broad resonances their energy and width can be found from the fitting of the experimental phase shifts using the analytical expression for the elastic scattering $S$-matrix. We compare the $S$-matrix pole and the $R$-matrix for broad $s_{1/2}$ resonance in $^{15}$F.

I. INTRODUCTION

A analysis of the $S$-matrix pole structure is a powerful method in quantum physics. It is well-known that the poles of the $S$-matrix in the complex momentum (or energy) plane correspond to bound, virtual and resonance states. There is a well-known relation between the $S$-matrix and Jost functions, the singular solutions of the Schrödinger equation at $r = 0$. The conventional numerical method for bound states is to search for solutions, which only have an outgoing wave at pure imaginary momentum in the upper half of the momentum plane. The corresponding wave function is an exponentially decreasing solution when $r > 1$.

Virtual or resonance states are described by the wave functions containing only the outgoing wave as a point, which exponentially increases to the complex momentum. In the past (see [2] and references therein), the analytical continuation onto the unphysical energy sheet of the Lippmann-Schwinger as well as the complex momentum space Padé approximant-regularized equations were used to find the resonance properties. The normalization formula for the bound state vertex function in the complex momentum space was generalized in [2] for the resonant and virtual states.

Such states are considered as unaccomplished bound states. This means that a bound state pole should move down the positive real axis of the complex momentum plane while the interaction strength decreases. At some critical value of the interaction strength, the pole approaches the zero energy point, which belongs to the contour of integration. After a subsequent decrease of the interaction strength, the pole moves to the lower part of the complex momentum plane (unphysical energy sheet) dragging the integration contour in the Lippmann-Schwinger equation to secure the convergence of the integral. This leads to the appearance of an extra term in the right-hand-side of the equation, which is the residue of the integrand at the pole.

This method of the analytical continuation has been applied successfully to di erent physical systems. Unfortunately, it cannot be used directly in the case of charged particles. We should also note that a numerical form of the Fourier transform of the potential, which is an input in the Lippmann-Schwinger equations, is known only for a limited number of potentials.

The problem of the exponential increase of the Gamow resonance wave function in the asymptotic region can be solved by a complex scaling method based on the so-called ABC theorem [4]. This method consists of solving the Schrödinger equation on a ray in the first quadrant of the complex momentum plane rather than on the real axis of the coordinate. This ray can be obtained by the following transformation of the radial coordinate and the conjugate momentum: $r \rightarrow r \exp(i) \text{ and } p \rightarrow p \exp(i)$. As a result, the bound state spectrum is supplemented by the $S$-matrix poles situated in the sector delimited by the angle between the real axis and the ray in the fourth quadrant of the complex momentum plane. The axis rotation angle $\phi$ is limited by the position of the potential singularities in the radial complex plane. It is important that the complex scaling method can be applied to the case of charged particles. The method is valid because the Coulomb potential satisfies the scaling condition of the ABC theorem. An application of this method to resonances in nuclear reactions was presented in [4]. The numerical realization of this method is a rather complex one.

A few different techniques to determine the resonance energy, width and resonance wave function based on the solution of the Schrödinger equation have been previously suggested. In these methods the normalization of the resonant wave function is achieved using the Zeilovitch's normalization [5], which is difficult in practical realization due to slow convergence of the integrals. First we refer to the method of solution of the radial Schrödinger equation to determine the resonances suggested in [5]. In this
method the complex eigenvalue and the Gamow wave function can be found by integration of the Schrödinger equation imposing the boundary conditions in the origin and the asymptotic region. To solve the equation the Fox-G code in num erical method was applied and the logarithmic derivatives of the internal and external wave functions were matched. However, this method fails in the vicinity of the threshold, for broad and subthreshold broad resonances (imaginary part of the cm energy is larger than its real part) and antibound (virtual) states. We underscore also that this method can be applied only for the potentials with the same interaction radius because of the problem with numerical calculation of the exponentially increasing wave function. The application of the method for the unstable nucleus can be found in [7,8].

A pole search has also been used in [3] by solution of the Schrödinger equation with the short range interaction for the scattering wave function. The Zel'dovich's normalization procedure for the Gamow resonance wave function supplies the complex-energy M matrix. The norms of the Gamow resonance wave functions does exist for charged particles also [10,11]. The method allows one to nd resonance and even subthreshold resonances but it cannot be applied to the virtual states.

The method, which is also close to our approach, was discussed in [12]. The asymptotic wave function in this method contains auxiliary S-matrix which coincides with the physical S-matrix at the resonance poles at which the solution becomes pure outgoing wave. The method was applied for determining the low-energy 5He and 5Li resonance parameters [13].

In the present work, we demonstrate how to nd the poles of the S-matrix corresponding to bound, virtual and resonance states and the S-matrix residues in these poles by solving the Schrödinger equation with the nuclear plus Coulomb potentials using the analytical properties of the S-matrix. In contrast to the previously published methods, in our S-matrix pole method the normalization of the resonant wave function is based on the connection between the residue of the S-matrix in the pole and the asymptotic normalization coe cient (ANC). This relationship is universal and can be applied to bound, virtual and resonance (narrow and broad) states [11] making our technique universal, and that is the main distinction of our method from the previously published ones. The ANC is the amplitude of the tail of the bound, virtual or resonant wave function [11,12]. For the resonant states, the ANC is related to the resonance width [11]. The use of the ANC doesn't require the normalization of the state corresponding to the S-matrix pole and this why our method allows one to determine both narrow and broad resonances, and even antibound states.

A simple relation between the ANC (nuclear vertex constant) and the overall normalization of the peripheral astrophysical S-factor suggested in [12,14,15] makes it extremely im portant for obtaining astrophysical S factors. Note that the normalization method proposed by Zel'dovich [5] was generalized in [13] for the interaction potential with a Coulomb b tail.

The S-matrix pole method addressed here has been applied earlier to the virtual (singlet) deuteron and virtual triton with different short-range potentials. The results of the two-step Gamow state normalization for the virtual (bound) state of 3H were published in [14]. For charged particles, the virtual state becomes a subthreshold resonance [15]. Here we present new results for the subthreshold resonances for the ground state of 2H. We also calculate the ground and the excited states of 14N and the resonance states of 15F. Finally, our method is applied to the three lowest T = 1/2 states in 15Be and 11N. Considering the 1° state in 11N as an example, we demonstrate how to determine in a model-independent way the energy and width of the broad resonance using the S-matrix analytical structure, which includes the resonant pole. Moreover, we demonstrate that the potential S-matrix pole method addressed here gives the resonance energy and width, which are very close to the model-independent results obtained from the analytical expression for the S-matrix in the vicinity of a single pole [16].

We use the system of units in which c = 1.

II. A NUMERICAL CALCULATION METHOD

To describe the nuclear interaction we adopt the Woods-Saxon potential

\[ V_N(r) = V_0 \, V_{LS} (E \, S) \frac{2}{m} \frac{d}{dr} \frac{1}{1 + \exp\left(\frac{r - d}{a}\right)} \]  

where \( V_0 \) (\( V_{LS} \)) is the depth of the central (spin-orbital) potential; \( E \) is the orbital cm energy operator for the relative motion of the particles; \( S \) is the spin operator; \( m \) is the reduced mass; \( d \) is the di useness and \( R_H = r_0 A^{1/3} \) (\( r_0 \) is the radius parameter of the nuclear potential, \( A \) is the atomic mass number). The Coulomb b interaction potential is taken in the form

\[ V_C(r) = \begin{cases} \frac{Z_1 Z_2 e^2}{r R_C}, & r < R_C; \\ \frac{Z_1 Z_2 e^2}{r R_C^2}, & r > R_C; \end{cases} \]

where \( Z_1 \) and \( Z_2 \) are the charges of the particles; \( R_C = r_0 A^{1/3} \) (\( r_0 \) is the parameter of the Coulomb b radius).

The radial wave function \( u_1(r) \) for the partial wave with the orbital cm energy \( E \) is the solution of the radial Schrödinger equation \( \frac{d^2}{dr^2} + 2 \frac{m}{E} V(r) \frac{d}{dr} + \frac{1}{r^2} \left( \frac{l(l+1)}{r^2} - E \right) u_1(r) = 0; \)

Here, \( u_1(r) \) satisfies the standard boundary condition at the origin:

\[ u_1(r) |_{r=0} = 0; \]
To solve the boundary condition for the derivative of \( u_1(r) \), we analyze the behavior of the wave function near the origin. The sum of the potentials \( V(r) = V_N(r) + V_C(r) \) multiplied by \( r \) is linear. Therefore we choose the point \( r_0 \) near the origin, and denote \( k_0^2 = 2 \frac{E}{V(r_0)} \).

The solution of the Schrödinger equation

\[
\frac{d^2}{dr^2} + k_0^2 \left( \frac{1}{r} \right)^{1+1} u_1(r) = 0; \tag{5}
\]

which satisfies the condition \( u_1(0) = 0 \), is proportional to the function \( g_1(k_0 r) = k_0 r \frac{J_0(k_0 r)}{J_0(k_0 r)} \), where \( J_0(k_0 r) \) is the spherical Bessel function. Taking this into account, one can use the initial condition for Eq. \( 3 \) as follows

\[
u_1(r) = g_1(k_0 r), \quad u_1^0(r) = k_0 g_0^0(k_0 r_0); \tag{6}\]

Note that the energy \( E \) is negative for bound and virtual states and complex for resonance states. In the external region \( r > R_0 \), where the nuclear potential can be omitted with reasonable accuracy, the general solution of Eq. \( 3 \) is given by

\[
u_1(r) = u_1^{as}(r) = C_1(k) u_1^{(+)}(kr) C_1^{(*)}(k) u_1^{(*)}(kr), \tag{7}\]

where \( k = \frac{2}{C} \frac{E}{r_0} \). Here, \( C_1^{(*)} \) are the coefficients that can be found by matching \( u_1(r) \) to the solution in the internal region at \( r = R_0 \). The functions \( u_1^{(+)}(kr) \) can be written in terms of the regular \( F_1(\ ) \) and the irregular \( G_1(\ ) \) Coulomb wave functions

\[
u_1^{(+)}(kr) = e^{i\beta} [F_1(\ ) \pm i G_1(\ )]; \tag{8}\]

where \( \beta = \frac{Z_I Z_e e^2}{2} \) is the Sommerfeld parameter, \( \beta \) is the Coulomb phase shift given by \( \beta = \arg \left( 1 + \frac{1}{C} \right) \) and \( C = kr \). The asymptotic form of \( u_1^{(+)}(kr) \) is given by

\[
u_1^{(+)}(kr) \sim e^{ikr} \left[ \frac{1}{2} \right]^\frac{1}{2}; \tag{9}\]

\[
u_1^{(+)}(kr) \sim e^{ikr} \left[ \frac{1}{2} \right]^\frac{1}{2}; \tag{10}\]

The coefficients \( C_1^{(+)}(k) \) and \( C_1^{(*)}(k) \) are proportional to the corresponding Jost functions \( C_1^{(+)}(k) \) and \( C_1^{(*)}(k) \), respectively. We can solve the Schrödinger equation numerically and search for the energy at which the coefficient \( C_1^{(*)}(k) \) vanishes. This condition \( C_1^{(*)}(k) = 0 \) means that we are dealing with only the outgoing wave in the asymptotic region \( r > 1 \). Note that for virtual and resonance states the first term in Eq. \( 7 \) is much smaller than the second one, which makes it difficult to obtain a solution and an eigenvalue. To make sure that \( C_1^{(*)}(k) = 0 \), we calculate the ratio of the Schrödinger equation solution (for the sum of a nuclear and the Coulomb potentials) and the outgoing wave in the Coulomb potential. This ratio must approach a constant in the asymptotic region. We also check the equality of the logarithmic derivatives of \( u_1(r) \) and \( u_1^{(*)}(kr) \) at \( r = R_0 \). \( R_0 \) should be chosen a little larger than the radius of the nuclear potential. According to the scattering theory, the vanishing of \( C_1^{(*)}(k) \) at the positive imaginary semi-axis in the complex plane corresponds to the bound state, while that on the negative imaginary semi-axis corresponds to the virtual (bound) state. The resonant state is determined by the zero of \( C_1^{(*)}(k) \) in the fourth quadrant of the complex plane.

The S-matrix is the ratio \( C_1^{(*)}(k) = C_1^{(+)}(k) \), which has a pole at \( k = k_0 \). If \( C_1^{(*)}(k) = 0 \), then the poles of the S-matrix of the 1st order the residue at the pole \( k_0 \) should be

\[
\text{Res} (S_1(k_0)) = A_1(k_0) = \frac{C_1^{(*)}(k_0)}{C_1^{(+)}(k_0)}; \tag{11}\]

where \( C_1^{(*)}(k_0) \) is the derivative at the pole \( k = k_0 \). To nd \( A_1(k_0) \), we calculate \( C_1^{(*)}(k) \) close enough to the pole \( k_0 \). Then, we use the function

\[
C_1^{(*)}(k) = a_1(k) + a_2(k)k^2; \tag{12}\]

to obtain the coefficients of the expansion \( a_1 \) and \( a_2 \) for which \( C_1^{(*)}(k_0) = a_1 \). The described method is called the potential S-matrix pole method.

III. RESULTS

A. The bound states of \( ^{14}N \)

To show how the method works, we start from its application to the bound states of \( ^{14}N \) considering it as a two-body bound state \( ^{14}N = ^{13}C + p \). We assume that the proton in the \( 1p_{1/2} \) orbital is coupled to the \( 1s_2 \) ground state of \( ^{13}C \) to form the \( 1^+ \) ground state and \( 0^+ \) excited state of \( ^{14}N \).

To describe these states in the two-body (core + nucleon) approach, we choose the geometric parameter of the bound state \( W \) code-Saxon potential to be \( r_0 = r_2 = 1.2 \) \( fm \) and \( a = 0.5 \) \( fm \). The well-depth procedure providing the expectation value of energy leads to \( V_0 = 51.65 \) M eV and \( V_{ls} = 15.9 \) M eV for the \( 1^+ \) state and \( V_0 = 47.71 \) M eV and \( V_{ls} = 15.9 \) M eV for the \( 0^+ \) state. The coefficients \( C_1^{(*)}(k) \) and \( C_1^{(*)}(k) \) are found from the set of equations \( u_1(r_1) = u_1^{as}(r_1), u_1(r_2) = u_1^{as}(r_2) \) (\( u_1^{as} \) is the known asymptotic solution), where both the neighboring points \( r_1 \) and \( r_2 \) should be chosen in the asymptotic region. In this work we choose as an example \( r_1 = 0.5 \) \( fm \) and \( r_2 = 1.2 \) \( fm \).
and \( r_2 = 0.51 R_{max} \), where \( R_{max} = N R_N \). The parameter \( N \) should be big enough to fulfill the condition \( u_1(r_1) = u_1^{as}(r_1) = \text{const.} \) In Figs. 1 and 2, the wave function for the \( 1' \) state of \( ^{14}\text{N} \) and the ratio of the wave function to the W hittaker function describing its asymptotic behavior are shown. For the \( 0' \) state, the wave function and its ratio to the W hittaker function are very similar to those of the \( 1' \) state. From these graphs, one can conclude that the coefficient \( C_{1'}(k) \) is equal to zero and the wave function coincides with its asymptotic form when \( r > R_0 \).

From Eq. (7) we get that in the external region the radial bound state wave function is given by

\[
u_1^{bsas}(r) = C_1^{(+)}(k) u_1^{(+)}(kr);
\]  
(13)

where \( k = i b_s \) (\( b_s > 0 \)). Normalizing the bound state wave function to unity we can rewrite its asymptotic term as

\[
u_1^{bsas}(r) = b_s W_{bs, r^{1/2}}(2 \text{בד} r);
\]  
(14)

where \( b_s \) is the single-particle ANC, \( W_{bs, r^{1/2}}(2 \text{בד} r) \) is the W hittaker function determining the radial shape of the bound state wave function, \( b_s \) is the Coulomb parameter for the bound state, \( b_s = \frac{2}{12} b_{bs} \) is the bound state wave number and \( b_{bs} \) is the binding energy of the bound state. For the adopted geometric parameters, we get \( b_{(gr)} = 4250 \text{ fm}^{-1/2} \) for the ground state and \( b_{(exc)} = 2457 \text{ fm}^{-1/2} \) for the excited state. Note that the single-particle ANC is sensitive to these parameters [22].

The residue at the bound state pole of the \( S \)-matrix is given by [13]

\[
A_1(k_0) = (1)^{1/2} i b_s^2;
\]  
(15)

Our calculated residues of the \( S \)-matrix at poles related to the ground and excited states give the values \( A_{gr} = 18.61 \text{ fm} \) and \( A_{exc} = 6.039 \text{ fm} \), respectively. Found from these residues, the single-particle ANCs coincide with \( b_{(gr)} \) and \( b_{(exc)} \) given above and found from the bound state wave functions. This validates the method of calculation of the residue of the \( S \)-matrix at the bound state pole presented here.

### B. Virtual (antibound) state

Here we apply our method to obtain the energy of the virtual (antibound) state in the \( np \) system at \( l = 0 \), taking into account only the short-range Yukawa nuclear potential \( V(r) = V_0 r^{-1} \exp(-r/R) \). The virtual state corresponds to \( k = i (j > 0) \), i.e., the pole of the \( S \)-matrix is located on the negative imaginary semi-axis in the complex momentum plane. It generates the exponentially increasing term \( u_0^{(+)}(kr) \) when \( r \rightarrow \infty \) while the second term \( u_0^{(+)}(kr) \) become exponentially small making it very difficult to determine the energy (momentum) when \( C_0^{(+)} = 0 \), which is the condition for the virtual pole. For this reason, to calculate \( C_0^{(+)}(i) \), one should obtain a solution with very high precision. In our calculations, the energy \( j \cdot (N + j) \) of the virtual state calculated as function of \( R_{max} = N R_N \) decreases smoothly as \( N \) increases. However, when \( N > N_{max} \) the energy exhibits a sudden change to the larger value. It means that for \( R_{max} \) the solution is not precise enough to calculate \( C_0^{(+)}(i) \) accurately. That is why we adopt \( n_p = \sqrt{N_{max}} \) as the virtual pole energy. Our result \( n_p = 0.67 \text{ MeV} \) agrees very well with the one obtained using the integral equation method [12,23]. The calu-
lated residue of S-matrix in pole is $A_{np} = 0.0721$ fm$^{-1}$ leading to the single-particle ANC for the virtual n p state

$$b_0 = 0.268 \text{ fm}^{1/2}.$$ 

C. The resonance states of $^{15}$F($1^{-}; 5^{-}$)

Several articles were published recently \[24,25,26,27,28\] testing the predictive power of the current theoretical approaches to describe the lowest broad levels in $^{15}$p. The main goal of these analyses was a comparison of the predictions with the available experimental data on the $^{15}$F levels. Determination of a broad resonance parameter is a well-known unsolved problem in physics. The resonance energy and width for a broad resonance are not defined uniquely and there are many prescriptions, which have been used in literature \[28\]. The definitions depend not only on the model used, say potential, S-matrix, macromolecular, but even within a given model the prescriptions for the resonance parameters can be different \[28,30\]. For example, in [31] four different definitions were used. In \[28\] two more definitions were added in the S-matrix approach. That is why we believe that, when any compilation includes the broad resonance parameters, the reference should be done to the prescriptions used to determine these parameters. The reason for this ambiguity is that for broad resonances in the physical region the nonresonant contribution becomes comparable with the resonant one. In this case the determined resonance energy and width depend on how much of the background is included into the resonant part. The only way to determine correctly the resonance energy and width is to single out the resonance pole explicitly in the function of the experimental data. It is realized in the S-matrix pole method.

Here we address two approaches based on the definition of the resonance energy $E_R = E_0 - \frac{1}{2}$ as the energy at which the S-matrix has a pole on the second energy sheet (low half of the complex plane): the potential approach based on the solution of the radial Schrödinger equation and the analytical expression for the S-matrix. The first one gives the most accurate definition of the resonance energy and width within the potential model, while the second one even more generally because it is based only on the analyticity and symmetry of the S-matrix \[19\].

We remind that a resonance corresponds to the pole of the S-matrix at $k_R = k_0 / (k_0 + k_1)$ and is located in the fourth quadrant of the complex plane. Correspondingly the resonance energy is

$$E_R = \frac{k_0^2}{2} = E_0 - \frac{1}{2};$$

(16)

where

$$E_0 = \frac{k_0^2}{2} \frac{k_1^2}{2};$$

(17)

and

$$= 2k_0 k_1;$$

(18)

For broad resonances $k_1$ becomes comparable with $k_0$ or even larger ($k_0 \cdot k_1$). If $k_1 > k_0$, i.e. the resonant pole in the complex m on the plane, due to large $k_1$, is far from the real energy axis and the energy of the broad resonance, $E_0 < 0$, is located in the third quadrant on the second energy sheet and we call it the subthreshold broad resonance \[24\]. Due to large $k_1$ (or resonance width $k_0$), the impact of the resonant pole on the cross section or scattering phase shift is weakened and the non-resonant amplitude or phase shift (non-resonant background) becomes important. The general expression for the elastic scattering S-matrix based on its analyticity and symmetry in a vicinity of a single resonance can be written as

$$S(k) = e^{2i \pi (k)} = e^{2i} \pi (k) \frac{(k - k_0)(k + k_0)}{(k - k_0)(k + k_0)}$$

(19)

where $\pi (k)$ is the non-resonant scattering phase shift,

$$\pi (k) = \arctan \frac{k_1}{k_0}$$

(20)

$$= \frac{1}{2} \arctan \frac{k}{k_1}$$

(21)

is the resonant scattering phase shift \[32,33\] and

$$= \arctan \frac{k_1}{k_0}.$$ 

(22)

For narrow resonances, $k_1 << k_0$, the phase shift $\pi (k) << 1$ can be neglected. In this case, the standard method, which we call the phase shift method (or $" = 2\pi \text{rule}\) entails the resonance energy $E_0$ the value at which the scattering phase $\pi (k)$ passes through $=2$. The resonant width is evaluated from the formula $= 2\text{d} = \frac{-dE}{dE} \text{at } E = E_0$ or as the energy interval corresponding to change of $\pi (k) = 4$ to 3. However, for broad resonances $\pi (k)$ cannot be neglected and the total non-resonant scattering phase shift $\pi (k) + \pi (k)$ becomes dependent on the resonance parameters. This non-resonant scattering phase shift may be a large negative so that the total phase shift $\pi (k)$ cannot reach $=2$ at $k = k_0$ making the $=2\pi$ method non-applicable. When calculating the elastic cross section or scattering phase shift in the presence of the broad resonance, due to the importance of the non-resonant phase shift, the cross section depends not only on the resonance parameters $E_0$ and $k_0$ but also on the potential adopted.

Here as a test case we select resonances representing the ground state $1^{-}$ and the first excited state $5^{-}$ in $^{15}$F. The latest very detailed analysis of the angular distributions for the $^{12}$C($d,p)^{13}$C reaction \[32,33\] shows...
that the spectroscopic factors for the ground 1=2\(^{-}\) and the 
1st excited state 5=2\(^{+}\) are close to the single particle 
one (0.99 and 0.90 respectively \[24\]). One expects the 
similar numbers for the mirror states in \(^{15}\text{F}\). Therefore, 
the potential approach is appropriate to describe these 
states. In \[24\] the W odd-Saxon potential parameters 
describe the excitation energies of the mirror levels in \(^{15}\text{C}\) 
and \(^{15}\text{F}\) as well as the experimental data on resonance 
\(^{14}\text{O}\) + p were found. The authors \[24\] presented the 
new data on the resonance parameters for the 1st two levels 
in \(^{15}\text{F}\) using the calculations of the wave function inside 
the nucleus, at the radius of 1 fm. The energy at which 
the absolute value of the wave function reaches its maximum 
was identified as the resonance energy. We call this 
the \(j_{\text{max}}\) method. In \[24\] the width of the resonance 
was defined by the energy interval over which the amplitude 
fails by 2 relative to the maximum of \(j_{\text{max}}\). For comparison, 
in \[24\] some results were presented using 
also the \(=2\) method.

We apply the potential \(S\)-matrix pole method by solving 
the Schrödinger equation with the W odd-Saxon potential 
given in \[24\] for both \(^{15}\text{F}\) resonance states with the 
\(J = 1=2\) and 5=2\(^{+}\). We search for the complex energy 
at which the co-efficient \(C_{11}^0 = 0\) (see Eq. \[1\]) similar 
to the search for the bound or the virtual state. We note 
that in the standard approach the scattering wave function 
is calculated at real energies, where the non-resonant 
contribution is significant for broad resonances, while the 
Gamow wave function is calculated at the complex energy 
corresponding to the resonant pole of the \(S\)-matrix 
located on the second Riemann energy sheet. As a first 
approximation, to determine the complex resonance energy 
\(E_{R}^0 = E_{R}^0 + i\)(\(=2\)) we use the phase shift method 
(or the \(j_{\text{max}}\) method when the \(=2\) method is nonapplicable). 
A faster way, we solve the Schrödinger equation 
with the complex energy \(E_{R}^0 = E_{R}^0 + i\)(\(=2\)). The 
real part of this result is the complex energy \(E_{R}^0\), at 
which the co-efficient of the incoming wave vanishes. 
We also applied the \(S\)-matrix pole search using the analytical 
representation \[15\] for the \(S\)-matrix (see explanation below).

Our results for the energies and widths of the 
resonance states are given in Table \ref{table1} compared with the 
previous results obtained using the \(=2\) and \(j_{\text{max}}\) methods \[24\]. The position \(E\) and the width \(\Gamma\) of the 
broad resonance depend on the calculation method: the 
\(S\)-matrix pole method gives the values of the resonance 
energy and width smaller and more accurate than the 
\(=2\) and \(j_{\text{max}}\) methods. It is worth noting that 
the corrected value of 1.227 MeV for the resonance energy 
of the ground state of \(^{15}\text{F}\) is very close to the lower 
limit given by Fortune \[24\] obtained using the isobaric 
multiplet method. Besides, in the most recent 
experimental work on \(^{15}\text{F}\) \[24\] it was indicated that the 
ground state energy of \(^{15}\text{F}\) can be even lower.

Figs. \ref{fig1} and \ref{fig2} show the real and imaginary parts of the 
normalized Gamow wave function for the 1=2\(^{-}\) and 5=2\(^{+}\) 
resonance states in \(^{15}\text{F}\). The solution of the Schrödinger 
equation coincides with the outgoing wave outside the 
potential area. We conclude that the probability of 
scattering the proton inside the potential area is relatively high. 
The advantage of our method is that we directly find 
the complex energy of the resonant state (energy and width) 
by the same procedure as for the bound state.

An important test of our method is comparison of the 
single-particle ANC determined as an amplitude of the 
transition probabilities for the bound state \(^{15}\text{F}\) ground \(S\)-matrix pole 
method by \[34\] in Ref. \[24\].

\begin{table}

\textsuperscript{a} It was a misprint = 0.225 MeV for the state \(1=2\) \(j_{\text{max}}\) in Ref. \[24\].
1. Model-independent determination of the energy and width of the broad resonance \( \frac{1}{2}^+ \) in \(^{15}\text{F}\).

The limitations of the potential model and the existence of the phase-equivalent potentials calls for a cross check of the energy and width for the broad resonance determined from the potential approach. We demonstrate how to determine these resonance parameters using the model-independent representation of the elastic scattering S-matrix given by Eq. (19). Since the experimental \( 2S_{1/2} \) phase shift for \(^{10}\text{C} + p \) scattering in the resonance energy region is not available, we generate the "quasi-experimental" \( 2S_{1/2} \) phase shift using the Woods-Saxon potential from [34], which reproduces the \(^{14}\text{O} + p \) resonance scattering. Its geometry is \( R_0 = 1.17 \text{ fm} \), \( a = 0.735 \text{ fm} \), \( R_C = 1.21 \text{ fm} \) and the depth \( V_0 = 53.52 \text{ MeV} \). The phase shift is shown in Fig. 3. Using the S-matrix pole method from the solution of the Schrödinger equation we find the resonance energy for this potential \( E_0 = 1.198 \text{ MeV} \) and the resonance width \( \Gamma = 0.530 \text{ MeV} \). Now we demonstrate that using Eq. (19) we can determine the "quasi-experimental" phase shift and determine the resonance energy and width. The potential phase shift in Eq. (19) is approximated by the polynomial

\[
p(k) = \sum_{n=0}^{\infty} b_n (k - k_0)^n.
\]

So, we have 6 fitting parameters including 4 coefficients \( b_n \), \( E_0 \) and \( \Gamma \). The final result does not depend on the choice of the center of the Taylor expansion \( k_0 \) and practically not sensitive to the starting values of \( E_0 \) and \( \Gamma \). We take here the starting values \( k_0 = 0.25 \text{ fm} \); \( E_0 = 1.45 \text{ MeV} \) and \( \Gamma = 1.376 \text{ MeV} \) obtained from the method, Table I. The Taylor to the "quasi-experimental" phase shift gives the resonance energy \( E_0 = 1.194 \text{ MeV} \) and \( \Gamma = 0.531 \text{ MeV} \) which is in a perfect agreement with the results obtained using the potential S-matrix pole method. For the start-

**Fig. 3:** Real (a) and imaginary (b) parts of the wave function of the 1-2' resonance state in \(^{15}\text{F}\). The solid line is the solution of the Schrödinger equation, the dashed line is the outgoing Coulomb function (the Whittaker function).

**Fig. 4:** The same as in Fig. 3 but for the 5-2' resonance state in \(^{15}\text{F}\).
ing search values $E_0 = 1.5$ MeV and $= 1.276$ MeV we get the fitted energy $E_0 = 1.198$ MeV and $= 0.532$ MeV. Thus Eq. (19) allows one to obtain the energy and width of the broad resonance using, for example, as input parameters the resonance and width obtained by the $= -2, j_{max}$ The model-independent result obtained from Eq. (19) gives very close values to the potential $S$-matrix pole. Assigning a 10% uncertainty to the "quasi-experimental" phase shift results in a similar uncertainty in the determined "quasi-experimental" phase shift resonance energy and width.

2. Comparison with $R$-matrix approach

The resonant $S$-matrix obtain from the $R$-matrix contains the nonresonant contribution through the energy dependence of the level shift and resonance width. The extrapolation of this functions to the complex energy plane is made with complex polynomials, i.e., they lose their physical meaning. Thus the $R$-matrix approach is not designed for extrapolation to the resonant pole.

Here we apply the $R$-matrix approach to determine the energy and the width of the resonance width the $S$-matrix pole method. For an isolated resonance in the single-level, single-channel $R$-matrix approach with the zero boundary condition the Coulomb-modified nuclear scattering $S$-matrix is

$$S = e^{i\phi} = \frac{E_0 + i\frac{E_0}{2}}{E_0 + i\frac{E_0}{2}}$$

where $\phi$ is the hard-sphere scattering phase shift. To obtain this equation the linear energy dependence of the level shift function ($E$) is taken into account. Here, $E_0$ is the real part of the resonance energy. In the $R$-matrix $E_0$ is determined as $E + \gamma (E_0) = E_\infty$, $E$ is the $R$-matrix level energy. $\gamma (E_0) = 2\sqrt{\frac{1}{2}(E_\infty)}$ is the observable resonance width in the $R$-matrix approach depending on the energy and the channel radius $r_0$, $E$ is the observable reduced width amplitude, $P_i(E; r_0)$ is the penetration factor in the $i$-th partial wave. The resonance width in the $R$-matrix approach, in contrast to the Breit-Wigner equation, depends on the energy. This dependence reflects the fact that the $S$-matrix in the $R$-matrix is richer than the Breit-Wigner equation; it includes also the non-resonant background, which is contributed by the hard-sphere phase shift and the energy dependence of the level shift function and the resonance width. For narrow resonance ($E_0 << E_\infty$) the pole in Eq. (23) $E_\infty E_0 i (E_\infty)$ is determined as $E_\infty = E_0 i (E_\infty)$, which is not a pole of Eq. (23). Hence, for broad resonances the difference between the resonance energy from the $S$-matrix pole method and the $R$-matrix pole method is expected.

To compare the results for the $R$-matrix and $S$-matrix pole methods for the $s_{1/2}$ resonance we use the phase shift generated by the Woods-Saxon potential from [2] as the "quasi-experimental" one and determine the resonance energy and width by fitting the $R$-matrix phase shift to the "quasi-experimental" case. The results are shown in Table 1. The $R$-matrix resonance energy and width found at $E_0 = 5.5\, \text{MeV}$ are higher than the $S$-matrix pole and close to the $j_{max}$ result. Both $R$-matrix and $j_{max}$ methods determine the resonance energy from the data at real energies where for broad resonances the contribution of the background becomes important. The $S$-matrix pole method determines the resonance energy and width by extrapolating the data to the pole in the complex energy (m cm inverse) plane in the vicinity of the pole the resonant contribution becomes dominant compared to the background and detuning of the resonance parameters is more accurate than in the physical region.

We made additional comparison of the $R$-matrix approach by fitting the data measured in [2] the excitation function of the $^{14}O + p$ scattering at $180\, \text{ degrees}$. Both resonances $s_{1/2}$ and $d_{3/2}$ coherently contribute to the excitation function. The resonances can be separated only after integration over the scattering angle. The selection of 180 scattering angles minimizes the Coulomb scattering effects and enhances the $d_{3/2}$ resonance contribution. The two-level $R$-matrix fitting to the excitation function gives the observables resonance energy and width presented in Table 2 for two channel radii $r_0 = 4.5$ and 6.6. The resonance energy is determined as the peak of the $\delta (k)_{1f}$ and the width as the FWHM of this function. We note

![Graph](image-url)
that this prescription differs from two prescriptions used in [34]. For narrow \( d_{l=2} \), all methods give very close results, but it is not the case for the broad resonance \( s_{l=2} \). The R-matrix results are between the j = as and the S-matrix pole. Since the S-matrix pole method based on Eq. (19) correctly takes into account the resonance contribution as a pole in the complex energy (m on en- tum ) plane and analytically continue it to the physical region, it allows one to separate correctly the non-resonant (background) contribution from the resonance one and, hence, provides the most accurate detemination of the resonance energy and width.

D. The lowest levels in the mirror nuclei \( ^{11}\text{Be} \) and \( ^{11}\text{N} \)

The light neutron rich nucleus \( ^{11}\text{Be} \) is probably the most discussed nucleus. The interest to \( ^{11}\text{Be} \) is related to the well-known inversion of the shell model levels in this nucleus. It has the following low-lying states: \( ^1S_0 \) (ground state), and the excited states \( ^1P_1 \) at \( 0.320 \) MeV and \( ^3P_1 \) at \( 1.778 \) MeV [35]. The \( ^1S_0 \) are the bound states while the third one is a resonance. As it was mentioned in [36], "the lowering of the \( s_{l=2} \) orbital with respect to the \( 0d_{5/2} \) orbital is expected for a simple potential well". The \( p_{l=2} \) state belonging to the \( K = 1/2 \) band has a pretty stable dominant [42] spatial symmetry congruence since the next \( 1d \) state is 10 MeV away [39]. In [39] was shown that the lowest \( p_{l=2} \) state obtained in a central potential with the spin-orbital interaction strongly overlaps with the state projected from a Slater determinant of the lowest orbits in the Nilsson's model with the same spin-orbital interaction as the shell model and deformation.

In this work to test our method we apply it for calculation of the three lowest states \( s_{l=2} ; p_{l=2} \) and \( d_{l=2} \) in \( ^{11}\text{Be} \) and \( ^{11}\text{N} \) nuclei belonging to the multiple \( T = 3/2 \). We also estimate the spectroscopic factors for \( s_{l=2} \) and \( d_{l=2} \) states using the potential approach leaving aside \( p_{l=2} \) state, which is not a single-particle [5].

Differential reactions, including the \( ^{10}\text{Be}(\text{d,p})^{11}\text{Be} \) reaction with the radioactive \( ^{10}\text{Be} \) target, were used to obtain the spectroscopic factors for the lowest states in \( ^{11}\text{Be} \). As a standard procedure, the single-particle neutron wave functions in \( ^{11}\text{Be} \) are used as the input in the DW BA code to get the neutron spectroscopic factors. The obtained spectroscopic factors are in the intervals (0.5-0.96) [40] and (0.7-0.8) [41]. But they are model-dependent because they depend on the Woods-Saxon potential adopted for the neutron bound state in \( ^{11}\text{Be} \) optical potential in the initial and final channels of the (d,p) reaction and accuracy of the DW BA to analyze for the deflated \( ^{11}\text{Be} \) [42].

A priori the transfer reactions involving deformed nuclei require the codes which take into account the multi-step transfer mechanisms, for example, the coupled channels Born approximation available in FRESCO. That is why it is difficult to say from the DW BA analysis to what extent the three lowest neutron states are single-particle.

The nucleus \( ^{11}\text{N} \) is the mirror of \( ^{11}\text{Be} \), and it should have a similar level scheme. All states \( ^{11}\text{N} \) are unstable to proton decay. Therefore, their decay widths directly related to their single particle nature. Since the discovery of the ground state in \( ^{11}\text{N} \) in 1996 [43], the lowest levels in \( ^{11}\text{N} \) were studied in many works (see [44] and references therein). In this section, we apply the S-matrix pole method to study the broad levels in \( ^{11}\text{N} \). Simultaneously we attempt to nd restrictions on the single particle potentials related to the widths and excitation energies of the mirror states in \( ^{11}\text{Be} \) and \( ^{11}\text{N} \).

To determine the single-particle levels in \( ^{11}\text{Be} \) and \( ^{11}\text{N} \), we use the Woods-Saxon plus Coulomb potential similar to the ones used in [23,40,41,46]. The parameters of the potential are fitted to reproduce the energies of the low-lying states in \( ^{11}\text{Be} \). Then we use this nuclear potential plus the Coulomb potential to nd the mirror levels in \( ^{11}\text{N} \). We apply the pure single-particle approach as in [23,45].

The different sets of the potential parameters, which were used to predict the lowest levels in \( ^{11}\text{Be} \), are presented in Table I. As a starting point, the standard geometrical parameters \( k_0 = 1.25 \text{ fm} \), \( a = 0.65 \text{ fm} \) of the Woods-Saxon potential are used. Then, we vary the depth of the central potential \( V_0 \) and the binding energy of the ground state \( s_{l=2} \) of \( ^{11}\text{Be} \) (well-depth procedure). We find that, we vary the radius \( r_0 \) and the di useness parameter \( a \) to get the binding energy of \( ^{11}\text{Be} \) at the xed depth \( V_0 = 57.5 \text{ MeV} \) from the s-state at standard geometrical parameters. We use the same procedure for the \( p_{l=2} \) and \( d_{l=2} \) states. As shown in Table I, the adopted potential well is shallower for the \( p_{l=2} \) state than for the ground state, which re ects the inversion of the s and p levels. To reproduce the well-known energy of \( ^{3}\text{P}_{1/2} \) resonance (\( E_{\text{R}} = 1.275 \text{ MeV} \) ), we use the set of the potential parameters determined for the ground state \( ^{11}\text{Be} \) with addition of the spin-orbital potential. The fact that \( ^{3}\text{P}_{1/2} \) state has particle width provides for an additional criterion for the selection of the potential. As can be seen in Table I, the calculated single-particle widths for this state are larger than the experimental values of 100-20 keV [39] and 104-21 keV [47]. Taking into account that

\[
\exp = S_{\text{sp}}
\]

Theoretical predictions (see [34] and references therein). Smaller experimental uncertainties in the width of the $^1$ state result in stronger restrictions in the potential parameters.

The S-matrix pole calculations for the three states, which are all resonances, for the mirror $^{11}$N nucleus are made using the potential parameters for the $^{11}$Be nucleus by adding the Coulomb potential of the uniformly charged sphere of the radius parameter $r_0$ (Eq. (2)). The results are shown in Tables III and IV for two values of the radius of the uniformly charged sphere.

It is worth noting that in the case of the relatively sharp $^1$ resonance, the differences between calculations of the resonance energy and the width using the S-matrix pole and the phase shift are relatively moderate, 140 keV and 130 keV, correspondingly. However, these differences become significantly larger for the broad resonance $^2$ in $^{11}$N, up to 300 keV for the energy and 500 keV for the width. We note that for the same set of the potential parameters the S-matrix pole method gives energy and width smaller than those obtained by the phase shift. As for the $2s_{1/2}$ state in $^{11}$N, the phase shift never passes through $=2$ in agreement with the earlier observation by Barker [23].

The S-matrix pole method reveals the resonance pole for the state $^1$ in $^{11}$N. To check that we have found the pole correctly, we match the logarithmic derivatives of the solution of the Schrödinger equation and the G-matrix function in the asymptotic region. We also check the ratio of the solution to the G-matrix function, which must be constant at the asymptotic region. Let us consider the $^1$ state in $^{11}$N. By averaging the experimental data from Refs. [43,44,45,50], we obtain 3.72 ± 0.05 M eV for the resonance energy for this level and 0.55 ± 0.03 M eV for the width. We can conclude from Tables III and IV that the S-matrix pole method gives for the width 0.85 M eV resulting in the spectroscopic factor $S = 0.65$. The standard geometrical parameters $r_0 = 1.25$ fm and $a = 0.65$ fm provide for a good agreement with the average experimental energy for this level. Using these parameters (Table I), one can find the spectroscopic factor of 0.53 for the mirror state in $^{11}$Be. A summing that the spectroscopic factors should be the same for the mirror states, one can conclude that the average value of the spectroscopic factor $S = 0.59$ is a characteristic of the single-particle state for the $^1$ state in the mirror $^{11}$N and $^{11}$Be nuclei.

The experimental data for the broad $^2$ resonance state in $^{11}$N need careful consideration because the results reported in Refs. [43,44,45,50] are different due to different definitions of "energy" and "width" in these works. We nevertheless conclude that the resonance energy of this state is 22 M eV. As in [38] we use Eq. (29) to get the width of the $^2$ state in the potential approach. The spectroscopic factor $S = 0.65$ results in the width $= 0.85$ M eV for this state. This spectroscopic factor coincides with the shell model prediction for the analogous state of $^{11}$Be and our result is in good agreement with the one obtained in [38].

All available experimental data [43,44,45,50] give higher resonance energies of the $^1$ state in $^{11}$N than our cal-

We note that the potential found in [43] does not reproduce the experimental binding energy of the \( 
\frac{1}{2}^- \) state and resonance energy of \( \frac{3}{2}^- \) state in \( ^{11}\text{Be} \). Meanwhile the potentials given in Tables III and IV are used in [50] for 2s and 1d states both in \( ^{11}\text{Be} \) and \( ^{11}\text{N} \). Then, we assume that the potential with the standard geometry \( r_0 = 1.25 \text{ fm} \) and \( a = 0.65 \text{ fm} \) in Table IV is the "right" one. Note that the resonance energy and width obtained for this potential are very close to the average resonance energy and width shown in Table IV for 5 different potentials. This potential gives 1.062 MeV resonance energy, which is a pure single-particle energy. We observe that this energy is 0.04 MeV less than the "experimental" value of 1.072 MeV obtained for the potential adopted in [43]. This 0.04 MeV can be attributed to the non-single-particle admixture to the structure of the \( \frac{1}{2}^- \) state in \( ^{11}\text{N} \).

An estimation of the spectroscopic factor can be obtained from the consideration of the width of the state. The \( r_0 = 1.25 \text{ fm} \) and \( a = 0.65 \text{ fm} \) parameters generate 0.95 MeV for the \( \frac{1}{2}^- \) state width at the "experimental" resonance energy of 1.10 MeV. The ratio of 0.94/0.95 (the "experimental" width/calculation width) results in the spectroscopic factor of 0.88 for the adopted potential with the standard geometry. Hence we obtain much larger spectroscopic factors for the ground state in \( ^{11}\text{N} \) than for the \( \frac{1}{2}^- \) excited state.

As a final remark to this section, it is worth noting that the conventional potential approaches, which determine the resonance energy and width from the energy dependence of the phase shift or from the \( j_{max} \) method, may not give accurate results because of the distortion generated by the non-resonant background at physical energies. For example, \( j_{max} \) may reach a peak in the internal region at energy \( E_{0} \). In this sense the S-matrix pole is the most accurate method for a given potential because it determines the resonance energy and width by searching the resonant pole at complex energy, i.e., separates the resonant contribution from the background. We note that the resonance energy determined by the S-matrix pole method depends on the adopted potential. Moreover, the resonance parameters determined by the S-matrix pole method may differ from the ones determined from the R-matrix approach as we have seen for the \( ^{15}\text{F} \) case.

1. Model-independent determination of the energy and width of the broad resonance \( \frac{3}{2}^- \) in \( ^{11}\text{N} \)

Here we determine the resonance parameters for the \( 2s_{1/2} \) resonance in \( ^{11}\text{N} \) using the model-independent representation of the elastic scattering S-matrix given by Eq. [13]. We use the Woods-Saxon potential with the standard geometry \( r_0 = 1.25 \text{ fm} \),
The conversion is ensured in the case of the two-body model with the Yukawa potential can not be reproduced in this approximation. But it is limited by a pole located on the positive in u aginary axis, which is not a bound state pole. In the case of the pp system, the situation is simple because there is no bound state, so any pole on the positive energy axis is an unphysical one. Moreover, the region of the validity of the e ective-range approximation is limited by the condition \( |k| \leq k_{\text{ex}} \) where the e ective-range expansion converges. In the potential model with the asymptotic V(r) = const. r exp(-r), the value \( k_{\text{ex}} = 1/(2R) \) is the beginning of the dynamical cut on the imaginary axis in the complex k plane. In the case of charged particles, the number of roots is infinite (see [51]). In particular, as noted in [52], the sequence of poles located near the negative imaginary axis can be mistakenly identified as virtual (antibound) state poles known for the system without the Coulomb interaction.

Finding the pole by solving the Schrodinger equation is the most reliable way to compute that the pole found by a solution of K0k's equation [13] is not a false one. This was done in the present paper for the pp system with the Yukawa potential. Its param eters are taken from [51] for the singlet np system. We nd that \( k_{\text{pp}}^2 = (0.064, 10.082) \text{fm}^{-1} \) or \( E_{\text{pp}} = (106.7, 1435.5) \text{keV} \) for the pp ground state. After that, we have slightly changed the geometric param eters to describe the experiment pp scattering length and e ective range and the resolved Schrodinger equation gives \( E_{\text{pp}} = (138.16, 1463.24) \text{keV} \). This result also coincides with K0k's results. The pole for nn system is \( E_{\text{nn}} = 92 \text{keV} \). The resonance wave function contains the outgoing wave in the asymptotic region while the ingoing wave is absent. For the normalization of the wave function in this case we can not use the Ze'kovich procedure because \( R \exp(k_{\text{pp}}) \ll 1 \) (k_{\text{pp}}), however, we can nd residue at the pole. The residue in the pole corresponding to the subthreshold resonance is \( A_{\text{pp}} = (0.021 + 10.057) \text{fm}^{-1} \).

IV. CONCLUSION

In the present work we apply the S-matrix pole method to determine the energies of the bound, the virtual states and resonances. This method is based on a numerical solution of the Schrodinger equation. Usually this method is applied to the bound states, but here it is extended to the resonant and virtual states despite the fact that the corresponding solutions increase exponentially when \( r \rightarrow 0 \). The method turns out to be especially useful for broad resonances including subthreshold ones.
There are a few poles in the complex plane when applying the effective range theory and the number of the poles is determined by the maximum power $k^n$ used in the effective range expansion. An additional investigation should be done to select a physical pole. In our approach one gets no false poles, thus resolving any ambiguity problem appearing in the effective range approach.

In the case of the resonances potential models and R-matrix approach are commonly used to analyze the experimental data, and resonance parameters are determined from the data. For narrow resonances both approaches give accurate results. However, this is not the case for broad resonances. In this case, due to the distortion caused by the non-resonant background at physical energies, the resonance energy and the width determined from the fitting of the experimental data depend on the model and width within a given model the prescriptions to determine the resonance energy and width may be different. Usually researchers use different definitions of the resonance energy and width. Broad resonance parameters extracted from the experimental data are model dependent. For this reason, one should indicate the method used to determine them in any subsequent references.

Here we address two methods for determining the resonance energy and width from the pole of the S-matrix: the potential S-matrix pole method based on the solution of the Schrodinger equation and the S-matrix pole method based on the analytical continuation for the S-matrix to the resonant pole. We compare the results for the resonance parameters obtained from the different definitions of the resonance energy and width in the potential approach, the S-matrix pole methods and R-matrix method. Correct evaluations of the resonance parameters are important when comparing the experimental data, both for the tests of the isobaric multiplet mass equation and for detailed structure calculations of the exotic nuclei. The potential S-matrix pole method provides the most accurate resonance energy and width for a given potential. The second S-matrix pole method, which uses Eq. 1, is even more general because it does not require any potential model and is based only on the analyticity and symmetry of the S-matrix. In contrast to other approaches, the pole S-matrix methods allow one to correctly separate the resonance pole contribution and the nonresonant background.

Our approach has a potential of being extended to treat broad resonance populated in transfer reactions, where the half-energy shell resonant amplitude interferes with the half-energy shell nonresonant amplitude. At present there is a huge disagreement in the resonance parameters for broad resonances obtained from the resonance or direct reactions [44].
