We report on measurements of the cosmic x-ray induced \gamma-ray emission of Earth's atmosphere by the Large Area Telescope (LAT) on board the Fermi Gamma-ray Space Telescope. The LAT has observed the Earth during its commissioning phase and with a dedicated Earth-blem following observation in September 2008. These measurements yielded $6 \times 10^8$ photons with energies $> 100 \text{MeV}$ and 250 hours total livetime for the highest quality data selection. This allows the study of the spatial and spectral distributions of these photons with unprecedented detail. The spectrum of the emission (often referred to as Earth albedo $\gamma$-ray emission) has a power-law shape up to 500 GeV with spectral index $\Gamma = 2.79 \pm 0.06$.

I. INTRODUCTION

For an Earth-orbiting $\gamma$-ray detector such as the Large Area Telescope (LAT) on board the Fermi Gamma-ray Space Telescope (Fermi), the Earth is the brightest source in the sky due to its proximity. The $\gamma$-ray emission from the Earth is produced by cosmic x-ray interactions with the Earth's atmosphere, and is often called the Earth albedo. The vast majority of cosmic x-rays are protons and heavier nuclei. A cosmic $\gamma$-ray cascade, mainly through decay of neutral pions and kaons and through Bremsstrahlung of electrons and positrons (dominating at energies below $50 \text{MeV}$), leads to the kinematics of the collisions, the cross sections of these processes at high energies are peaked in the forward direction.
The spectrum of the albedo rays is not uniform across the Earth's disk. The spectrum of the inner part of the disk is soft owing to the small number of secondary particles, typically neutral pions, that are back-scattered at large angles relative to the direction of the cosmic ray cascade developing deep into the atmosphere. Cosmic rays that enter the atmosphere near grazing incidence produce showers whose forward-moving rays can penetrate the thin atmospheric layer making the limb bright when viewed from orbit. The geometric effect of shower production and absorption in the atmosphere producing a bright ray horizon was first calculated by Stecker. A Monte Carlo model of ray production by cosmic rays in the atmosphere was developed by Morris using approximately 6700 events towards the nadir direction. Also, they show a modulation of the ray intensity with respect to the east-west direction as expected from the detection of cosmic rays in the atmosphere's magnetic field. These findings were confirmed by other satellite missions and followed up by other satellite observations.

The Earth's -ray emission has been observed by several previous satellite missions starting as early as the 1960s with a detector on the third orbiting Solar Observatory, OGO-3, for energies above 50 MeV. This instrument detected an enhancement of -rays when pointing towards the Earth, consistent with balloon flight measurements and followed up by other satellite missions. A more detailed study of -ray emission from interactions of cosmic rays with the Earth's atmosphere was done by Thompoe et al. using approximately 6700 events from the Earth, recorded with the second Small Astronomy Satellite, SAS-2. These early measurements showed a clear peak of -ray intensity towards the Earth horizon, with a factor of 10 larger intensity than seen towards the nadir direction. Also, they show a modulation of the -ray intensity with respect to the east-west direction as expected from the detection of cosmic rays in the Earth's magnetic field. These findings were confirmed and extended to higher energies with the high-energy -ray satellite detector on-board the Compton Gamma-Ray Observatory (CGRO), the Energetic-ray Experiment Telescope (EGRET). EGRET was in operation from 1991 to 2000, and approximately 60% of the mission's total 15.2 million events were measured from the Earth direction.

The next generation -ray observatory, Fermi, was launched on 11 June 2008. The primary instrument on Fermi, the Large Area Telescope (LAT), is a pair-conversion telescope that detects -rays through conversion into an e-e pair. The trajectories of this pair are recorded in the tracker and allows for the reconstruction of the direction of the incident photon. The subsequent detection of the -ray photon in the LAT allows for the determination of the photon energy. The LAT's wide field of view (~2 sr), effective area (~8000 cm^2 at 1 GeV), inproved point spread function (PSF), and broad energy coverage (20 MeV to > 300 GeV) provide significant inproved sensitivity over its predecessors.

During routine science operations (the so-called "survey" mode), the LAT points away from the Earth because of the relative brightness of the Earth at GeV -ray energies and the background would introduce to astrophysical sources. The center of the -ray background from the LAT is kept within 35° relative to the zenith (the direction pointing away from the center of the Earth). However, during the commissioning phase of the LAT, the pointing was such that parts of the Earth were within the field-of-view at varying angles with respect to the LAT z-axis. In addition, during September 2008, a dedicated observation of the Earth's limb was made. This combined dataset can be used for the analysis of the Earth's -ray albedo emission.

There are several reasons that render a study of the Earth's -ray albedo useful. First, measurements of the albedo -rays contribute to the understanding of the celestial -ray background for the LAT and future satellite instruments. Second, such observations can be used for a calibration of the LAT instrument. Finally, if the production of secondary -rays in the Earth's atmosphere is sufficiently understood and modeled, observations of the albedo emission yield a measurement of the interactions of primary cosmic rays with the Earth's atmosphere and can, therefore, provide information on the spectrum of primary cosmic rays, interaction cross sections, atmospheric properties, and the detection of primary cosmic rays by the geomagnetic field.

The current work describes the analysis of the Earth's -ray albedo emission at energies above 100 MeV observed with the LAT.

II. DATASET

Two main data sets have been used: (i) the Launch & Early Operations (LEO) data taken during the first 60 days of the mission, during which the Earth limb was often closer to the field of view than during a regular sky survey (only data were used that were suitable for science observations), (ii) two orbits (i.e., close to 3 hours) of direct limb observations during which the Earth limb was kept within the field of view with the aim of adding on-axis photons to the overall data set. The LEO data contain many different observation modes, but the main modes are a north-pole-pole pointing and a pointing mode with the LAT z-axis centered on the Vela pulsar. All results shown here are averaged over any orbit of Fermi and correspond to the highest quality event selection currently available.
for the LAT data (the so-called \(d\)i use\) class events \([13]\)). The total number of events > 100 M eV in our dataset is 641 18 corresponding to 250 hours of livetime. The maximum total exposure is close to the Earth north pole with \(2 \times 10^{10} \text{ cm}^2 \text{s at } 1 \text{ GeV}\).

In addition to the standard di use cuts, corresponding to the post-launch instrument response functions P6V3, we applied the following selections:

\[
\text{LAT } < 65 \quad \text{to avoid the edge of the field of view of the LAT (LAT being the angle with respect to the LAT z-axis).}
\]

III. RESULTS

A. Intensity Maps

To generate intensity maps we transform the incident photon directions into the Earth-centric coordinate system with angles \(\text{nadir}\) and \(\text{nadir}\) denoting the zenithal and azimuthal angle about the direction pointing from the spacecraft towards the center of the Earth, where \(\text{nadir } = 0\) corresponds to the north. The photons were binned in solid angle for energy intervals with spacing 10 bins per decade from 200 M eV up to 500 G eV. The solid angle bins were spaced equally in \(\text{nadir}\) with an energy dependent binning in \(\text{nadir}\) changing from 1 at 200 M eV to 0.1 above 10 G eV to take into account the LAT’s energy-dependent angular resolution. The LAT pointing and livetime history were evaluated in the same coordinate system in 30-second time steps, creating maps of the exposure of the spacecraft to allow conversion from photon counts per solid angle to intensities.

Figure 1 shows the resulting exposure and photon intensity maps for 3 different energy bands (left: 200 M eV to 1 G eV, center: 1 G eV to 10 G eV, right: 10 G eV to 500 G eV). The center of each plot (i.e. \(\text{nadir } = 0\)) is the nadir direction, while the edge of the plots are the horizon at LAT’s altitude (\(\text{nadir } = 90\)). North is to the top of the maps and west to the left. All intensity maps have been background corrected by subtracting the average intensity from a ring between \(\text{nadir } = 79\) to 80 averaged over \(\text{nadir}\).

The exposure is a factor 2 higher in the north compared to south (top row). This is due to the observation strategy in which the majority of the data were taken during a north-orbital pole pointing. The exposure increases with energy due to the increase in the LAT’sective area. It can also be seen that towards the nadir the exposure is much lower than towards the rim. To avoid the introduction of large errors from low exposure bins in the spectral analysis, areas where the exposure is less than 0.5% of the maximum exposure in the corresponding energy band are excluded from the analysis in all energy bands. The discarded areas due to low exposure match the black regions in the center of the exposure maps. Com pared with EGRET, the LAT exposure is about a factor of 30 larger\([14]\).

The \(\gamma\)-ray intensity maps (bottom row) in units of photons cm\(^{-2}\) s\(^{-1}\) show the bright limb of the Earth, with the emission becoming less intense towards nadir. The Earth limb is very bright with intensities of up to 0.01 photons cm\(^{-2}\) s\(^{-1}\) in the low energy bands (more than one order of magnitude brighter than the center of the Milky Way for the same energy range. The narrowing of the emission with increasing energy is an effect of both the PSF of the LAT in proving at higher energies \([13]\) and the increasing contribution by \(\gamma\)-rays produced in the forward direction of the cosmic-ray showering at higher energies. Only 27 photons above 10 G eV are detected with angles \(\text{nadir } < 60\).

The maximum of the \(\gamma\)-ray emission is detected from a narrow region at \(\text{nadir } = 68\). The intensity maps also show significant modulation between east and west with the effect decreasing as the \(\gamma\)-ray energy increases (this is the so-called \(\gamma\)-east-west effect\(^*\)). Photons arriving from directions excluded from the analysis due to low exposure are not shown on the maps.

Our measurements are in good qualitative agreement with expectations from standard cosmic-ray air-shower phenomenology.

The east-west effect that can be seen in the lower energy intensity maps is due to the detection of cosmic \(\gamma\) rays in the Earth’s magnetic field. If there was no magnetic field, the cosmic \(\gamma\) ray intensities at the top of the atmosphere would be isotropic, and no east-west asymmetry would exist. However, the presence of the magnetic field biases the cosmic \(\gamma\) ray intensities interacting in the atmosphere. There are fewer cosmic \(\gamma\) rays interacting from an easterly direction than the west because the magnetic field disallows trajectories from the east. This effect is energy dependent so that low-energy cosmic \(\gamma\) rays are affected more than high-energy cosmic \(\gamma\) rays (those with energies above 50 G eV are unaected). Since the majority of the emission near the limb comes from viewing the development of the cosmic \(\gamma\) ray showers in the forward direction, the reduced cosmic \(\gamma\) ray intensity from the east actively suppresses the shower products coming from this direction. This effect vanishes when the atmospheric photons are predominantly generated by cosmic \(\gamma\) rays that have large enough energies to allow them to reach the atmosphere undetected by Earth’s magnetic field. This is the case for secondary photons with energies > 10 G eV.
The high-energy $\gamma$-rays ($E > 10$ GeV) are concentrated in a very narrow band toward, but not exactly aligned with, the Earth-limb angle, which is at $66.7^\circ$ for the LAT's orbital altitude of 565 km. At these high energies the number of back-scattered $\gamma$-rays formed in the shower development is negligible and the intensity is dominated by forward-emitted $\gamma$-rays from incident cosmic rays with tangential directions to the Earth's surface. Vertically incident showers have their first interaction in the range between 10 to 20 km, which corresponds to $\text{nadir} = 67^\circ$. The atmospheric column density in the limb direction is large, being many attenuation lengths of material, which suppresses the $\gamma$-ray emission close to the limb. In addition, the LAT views mostly grazing-incidence cosmic rays in the higher parts of the atmosphere. Therefore, the maximum of the emission is in the range between $\text{nadir} = 67^\circ$ to $69^\circ$. For zenith angles larger than about $\text{nadir} = 70^\circ$ the atmospheric depth is too small to produce a hadronic shower. For zenith-angles smaller than the limb angle at $\text{nadir} = 66.7^\circ$, the Earth and its atmosphere form an opaque barrier to forward-emitted $\gamma$-rays. Only the significantly lower-intensity back-scattered and $\phi$-axis emission from the cosmic-ray shower development is detected for these viewing angles. Thus, the maps above 10 GeV show a very narrow band close to but not at the Earth's limb.

### B. Spectrum

Figure 2 shows the LAT measured energy spectrum of the atmospheric $\gamma$-rays for different $\text{nadir}$ bands integrated over azimuth angles. The spectra have been corrected for spill-over effects due to the LAT PSF. This was done by measuring the intensity in each energy bin outside of the Earth limb, where very little emission is expected due to...
The significant lower atmospheric density outside of the rim is defined here as \( 70 < \theta_{\text{nadir}} < 73 \). Only for the low energy part of the spectrum (below 1.5 GeV) this spillover effect is relevant. Beyond that energy the intensity outside the rim is lower by many orders of magnitude than the intensity from inside the rim.

The average differential spectrum of the limb region (open circles), i.e. for \( 66 < \theta_{\text{nadir}} < 70 \), shows evidence for a turnover at energies below 3 GeV. Between 3 GeV and 500 GeV the spectrum can be fitted with a power-law \( dN/dE = I_0 E^{-2.75} \) with normalization \( I_0 = (7.4 \pm 1.0) \times 10^6 \text{ MeV}^{-1} \text{cm}^{-2} \text{s}^{-1} \text{sr}^{-1} \) and photon index \( = 2.79 \pm 0.06 \). Since both the intensity and the exposure vary considerably over the limb region, a derivation of the statistical errors is not straightforward. To determine the statistical errors we use a Monte Carlo technique: 1000 pseudo-count experiments are generated for each energy bin, using the LAT exposure and a model of the gamma-ray intensity emitted by the Earth albedo derived from EGRET observations [14]. In this model, the average intensity from the
In the LAT data set, the systematic errors dominate over the statistical errors nearly up to the highest energies.

The bottom panel of Fig. 6 shows the differential intensity multiplied by $E^{2.75}$ (the spectral index of cosmic-ray showers) for the LAT data. The integrated intensity of Earth's limb above 100 MeV is $5.2 \times 10^3 \text{ cm}^{-2} \text{s}^{-1} \text{sr}^{-1}$, which makes Earth by far the single brightest source in the LAT energy range. For this data set, there are 16 photons above 500 GeV and 3 events above 1 TeV with the highest energy photons having an energy of 1.14 TeV. Events above 500 GeV have not been used in the spectral analysis since the energy calibration of the LAT is still under investigation at these energies. Also shown are solid circles and dots are the spectra for two inner regions of the Earth's disk (60 < $\text{nadir}$ < 66 and 30 < $\text{nadir}$ < 60). The spectra become much softer above a few hundred MeV when moving towards the inner part of the disk. Fitting the inner parts by a power-law with energy-dependent index of the form $dN/dE = 1_{0}E_{\text{cosm}}^{1_{0}}(E-0.1 \text{ GeV})^{1_{0}}$ yields $7.76$ for the range between 60 < $\text{nadir}$ < 66 and $6.9$ for the range between 30 < $\text{nadir}$ < 66.

The spectrum of Earth's limb above 100 MeV is dominated by cosmic-ray interactions in the upper atmosphere layers (in tangential directions) pointed towards the LAT that do not suffer large energy losses in the atmosphere (as compared to the back-scattered -rays). At high-energy showers (above 3.2 GeV) the spectrum enters the region of cosmic-ray primary (at 10 GeV) unaected by the Earth's magnetic field, and therefore, should have a spectral index close to that of cosmic-rays [13]. The fitted power-law index of the atmospheric -ray emission from the limb is $2.75$ for 90 degrees of freedom (when using only systematic errors).

The spectra are qualitatively similar when taking into account the region for which the SAP-2 spectrum had been derived (10 degrees around the Earth's limb). The differences in the measured $\nu_{\text{e}}$ could be due to the limitation of the LAT resolution of 120 degrees or the fact that the PSF is folded into the integration region, the match in areas over which the measurements were taken is not perfect.

**C. Azimuthal and Zenithal profiles**

Figure 3 shows an azimuthal profile of the limb emission (i.e., for 60 < $\text{nadir}$ < 75) for four different energy bands (0.2-1 GeV, 1-10 GeV, 10-30 GeV, and above 30 GeV). As can be seen, the east-west effect is a very prominent modulation at low energies with a factor of 5 intensity difference between the minimum in the east (at $\text{nadir} = 90$) and the maximum in the west (at $\text{nadir} = 270$). This factor is consistent with what has been shown for EGRET data [14]. The difference in intensity between the east and the west for the highest energy band is consistent with no modulation (8.0 ± 2.9) $10^{7} \text{ cm}^{-2} \text{s}^{-1} \text{sr}^{-1}$ from the east and (10.0 ± 2.0) $10^{7} \text{ cm}^{-2} \text{s}^{-1} \text{sr}^{-1}$ from the west. The no-modulation hypothesis provides an acceptable fit only for the > 30 GeV band ($\chi^2 = 74$ for 71 degrees of freedom). All other bands show the variation in intensity with azimuth and hence a poor fit to a constant (for example, the 10-30 GeV band has a $\chi^2 = 188$ for 71 degrees of freedom). A comparison between the intensity from the north and the intensity from the south is consistent within errors (variation is below 15%). The behavior of these azimuthal variations can be qualitatively understood taking into account the production mechanism. High-energy cosmic-ray showers products are altered by Earth's magnetic field and due to their predominately positive charge preferentially select particles coming from west. Higher-energy cosmic rays have higher magnetic rigidities and are therefore less affected by Earth's magnetic field.

Figure 3 shows the zenith angle distribution for several energy bands separated into angular segments of 90 degrees referenced to the nadir centered on the directions north, east, south, and west. These plots have been background subtracted by taking the average intensity in the wedge at $\text{nadir} = 80$ (beyond the Earth's disk) as a background estimation.
The angular distribution of photons near the rim can be used to compare the hard photon emission with a simple atmospheric model to investigate the effect of the absorption of γ-rays. The proton-air interaction length is $X_{\text{I}} = 85$ g cm$^{-2}$, which can be estimated using the value $275$ m b for the total inelastic $^3$He-N cross section $[23]$. In the thin target regime, where the atmospheric depth is $X_{\text{I}}$, the intensity of produced γ-rays is $\propto X$. A competing process is the attenuation of γ-rays due to the e$^+e^-$ pair production, with the corresponding scale, the radiation length, of $X_0 = 38$ g cm$^{-2}$ in the atmosphere $[23]$. The interplay between these processes sets the value of column density when the e$^+$e$^-$ absorption of γ-rays becomes noticeable $\sim 10$ g cm$^{-2}$.

Indeed, this behavior is demonstrated in Figure 3, which shows the integrated atmospheric column depth along the line of sight for a given nadir angle at a height $560$ km for two different atmospheric models. The solid lines show the curve for a simple model of the atmosphere with an exponential density profile with scale height $6.8$ km $[23]$ following the barometric formula $X(h) = X(h=0) e^{(h+h_0)}$ with $X(h)$ in units of g cm$^{-2}$ denoting the column density of air overlying a point at altitude $h$ in cm. The dashed line shows a more realistic atmospheric model (NR0LM SISE-00) as given by Pione et al. $[23]$. Overlaid on the atmospheric column densities is the γ-ray intensity (scaled to match the barometric atmospheric profile) averaged over all theta angles (solid circles). Also shown is the convolved LAT intensity (open circles) in these angles for the PSF at the median energy of this data set ($4.7$ GeV). The plot shows that far enough out beyond the rim (in the plot for angles $\theta_{\text{nadir}} > 68.3$), the γ-ray intensity follows closely the column density. This region is the thin-target regime, in which the attenuation of γ-rays is not important yet and the intensity scales directly with the amount of atmosphere for the proton-air interaction. For column densities larger
Figure 4: Average intensity as a function of nadir angle in wedges towards the different directions (north, west, south, east) for 4 different energy bands. The narrowing of the emission with increasing energy is seen as well as the change in shape (with a broad tail towards the center of the Earth for low energies) and a very narrow lobe for the high energies. The comparison of the PSF calculated for the lower bound of the energy bin (averaged between front and back-converting events) is shown as a dashed line. Note that the range of the histogram and the binning is different for the two high-energy bands.

than 10 g cm$^{-2}$ the atmosphere starts to be optically thick for -rays and absorption (i.e. a deviation from the scaling with density) sets in.

If the target is thin enough that the secondary -rays are practically not attenuated, the observed -ray intensity should have a power-law index close to the index of ambient cosmic rays. Indeed, it has been shown that the assumption of a constant fraction 0.17 of energy of the incident proton released in the secondary -rays (function approximation) works well in proton-proton interactions for 1 GeV - 100 GeV $^{13,24}$. The Earth's atmosphere consists predominantly of N and O, and there is a significant fraction of He in cosmic rays. This difference in the beam and target composition could be taken into account by introducing an approximate energy independent correction factor, but we are currently interested in the spectral slope and not in the absolute normalization of the -ray intensity. Therefore, a comparison of the ambient spectrum of protons, with the energy scaled by a factor of , with the observed spectrum of -rays may be used to check the equality of their spectral indices and to test the energy calibration of the LAT instrument.

Figure 6 shows the -ray spectrum for the optically thin region (68° < nadir < 69°) compared to the proton spectrum with the energy scaled by a factor of . The proton intensity is scaled by first scaling the energy of each intensity point by a factor , and then re-normalizing the resulting proton intensity down by 0.7. In this way the proton intensity matches the -ray intensity at 1 GeV (i.e., the ratio is normalized to unity at 1 GeV). The general good agreement is further demonstrated by the inset in Figure 6 which shows the ratio of the -ray intensity to the scaled proton intensity.
FIG. 5: Comparison between the integrated column density with the LAT-detected gamma-ray intensity as a function of nadir angle for events above 3.6 GeV. Two different model atmospheric profiles have been used: a simple barometric atmosphere with scale height of 6.8 km [22] shown as solid line and a more realistic atmospheric model from [23]. Shown are the measured gamma-ray intensity (solid circles) and the gamma-ray intensity deconvolved by the PSF of the median energy (4.7 GeV) of this data set (open circles). A good correspondence between the gamma-ray intensity and the column density can be seen at angles $\Theta_{\text{Nadir}} \approx 68^\circ$. For these angles the atmosphere is thin enough (column density $< 10^4$ g cm$^{-2}$) so that no significant attenuation occurs and the gamma-rays are directly related to the amount of target material for the incoming cosmic rays. The absolute level of the gamma-ray intensity has been scaled to match the column density for the barometric atmosphere model.

IV. CONCLUSION

Data from the LAT have been used to study the gamma emission generated in the interactions of cosmic rays with the Earth's atmosphere for energy one to four orders of magnitude between 100 MeV and 1 TeV with unprecedented precision. The data set contains 218 photons above 100 GeV, and 16 photons above 500 GeV. These measurements therefore demonstrate the capability of the LAT to detect and determine energies for photons up to TeV energies. Two-dimensional intensity maps as well as azimuthal and zenithal profiles and energy spectra of the Earth albedo emission have been derived which show several ects:

A bright limb at the Earth's horizon. These limb gamma-rays are dominantly generated by grazing-incidence cosmic-ray showers coming directly towards the LAT. The gamma-ray spectral index follows the spectral index of the incident cosmic-ray spectrum in the limb region up to gamma energies of $E < 100$ GeV.

A soft-spectrum nadir region dominated by gamma-rays back-scattered at large angles originating from cosmic-ray showers developing deep into the atmosphere. Due to increasing collimation of secondary particles with increasing energy, these gamma-rays show a much softer spectrum.

An east-west modulation for energies below 10 GeV, caused by the detection of primary cosmic rays in Earth's magnetic field. Higher energy cosmic rays are less affected by the magnetic field, resulting in a fading
Figure 6: A comparison of the measured gamma-ray intensity for the angular interval $68^\circ < \theta_{\text{rad}} < 69^\circ$ (thin target case, gamma-ray attenuation is insignificant) with the scaled cosmic ray proton intensity (see text for details). The inset shows the ratio between the -ray data and the scaled proton data and shows the general good match between the two measurements. The data have been taken from Sanuki et al. [18] and Ryan et al. [17].
