We have analysed the first 15 months of Fermi/LAT data of the radio loud quasar 3C 273. Intense gamma-ray activity has been detected, showing an average flux of \( \frac{1}{100 \text{ MeV}} = 3 \times 10^{-6} \text{ ph cm}^{-2} \text{ s}^{-1} \), with a peak at \( \frac{1}{100 \text{ MeV}} = 5 \times 10^{-6} \text{ ph cm}^{-2} \text{ s}^{-1} \) detected during a flare in September 2009. Together with the brightening of the source, a possible hardening of the gamma-ray spectrum is observed, pointing to a shift of the inverse Compton peak towards higher energies than the 100 MeV range in which 3C 273 inverse Compton emission in typical to peak. During the 15 months of observations the photon index is measured to vary between \( \gamma = 2 \) and \( \gamma = 3 \), with an average value of \( \gamma = 2.78 \). When compared to the observations at other wavelengths, the gamma-rays show the largest \( \nu \alpha \) variations and we discuss the possibility that two different components are responsible for the inverse Compton hump emission below and above the MeV peak.

1. Introduction

3C 273 is a bright, radio loud quasar that shares most of the characteristics of blazars, like strong radio emission, a jet with apparent superluminal motion, large \( \nu \alpha \) variations, and, occasionally, polarization of the optical emission (see Courvoisier et al. 1998 for a review). On the other hand, this AGN presents also characteristics more common in Seyfert galaxies, like a prominent blue bump and the signature of non-therm al Comptonization processes in the X-ray spectrum.

3C 273 was the first extragalactic source to be detected at gamma-rays by COS-B observations in 1976 and later on was detected several times by the EGRET instrument on board the CGRO satellite. Thanks to its early discovery as a multiwavelength emitter and to its brightness, 3C 273 is one of the best observed AGN at all energies. The multiwavelength on-line database of 3C 273 (http://isdc.unige.ch/3c273/) contains about 40 years of data from radio to gamma-rays. This set of data constitutes a very precious starting point for studying the multi-band variability of this object. In particular, with the launch of Fermi in June 2008 an intense gamma-ray monitoring of the source has started and triggered observations along the whole electromagnetic spectrum, coordinated by several groups. This extensive and regular look at the source, together with the comparison with the historical long-term behaviour at all wavelengths, will allow us to investigate the properties and origin of the high-energy emission in greater detail than it had ever been done before.

2. From radio to X-rays

2.1. The 3C 273 multiwavelength database

The 3C 273 database, first created in 1999, has been recently updated with observations up to 2007 in order to provide the community with one of the most complete multiwavelength databases for an AGN. At the time being the database contains 70 light curves covering 17 decades in energy and spanning up to 40 years of observations (Fig. 1). In addition, for the X-ray band, information about the spectral parameters used to extract the \( \nu \alpha \)es is also available. The bulk of the high-energy data has been collected in the last 10(15) years, thanks to the intense X-ray monitoring provided by Bepe...
The variability study

As a first application of the on-line database, we studied the variability properties of 3C 273 at different wavelengths and, correlating the behaviour in the different energy bands, we tried to identify the emission processes and understand their inter-connections.

The amplitude and the time scales of the variations of 3C 273 depend strongly on the frequency and show trends that are characteristic of the underlying emission processes (Fig. 2). For example, the increasing amplitude of the variations and the decreasing time scales when going from long radio to short millimeter wavelengths is the typical signature of the superposition of synchrotron axes from shock waves propagating along the jet.

The different variability properties in the X-rays below and above 20 keV seem to support the possibility of two separated emitting components, possibly non-thermal Comptonisation (as in Seyfert galaxies) and inverse Compton from the jet (as in blazars). As an alternative, a single component characterised by at least two independently varied parameters could also explain the X-ray timing properties.

In any case, the dominant hard X-ray (> 20 keV) emission is most probably not due to electrons accelerated by the shock waves in the jet as their variability does not correlate with the arising milli-steradian emission at short time lags (Fig. 3). Instead, the hard X-rays seem to be associated to long-time scale variations in the optical domain. This optical component is consistent with being optically thin synchrotron radiation from the base of the jet and the hard X-rays would be produced through inverse Compton processes (synchrotron self-Compton and/or external Compton) by the same electron population.

In the gamma-ray domain, the limited data available before AGILE and Fermi observations did not allow to draw a firm conclusion about the variability in the MeV–GeV energy range. The increase of the variability amplitude observed in the X-rays seems to continue up to the gamma-rays, possibly even above 100 MeV where the observed decrease is likely due to the large uncertainties of the EGRET sources (circles in Fig. 2).

3. The gamma-ray emission

3.1. Before Fermi emission

During CGRO/EGRET observations, 3C 273 was either found below the EGRET sensitivity level, or detected at a relatively low gamma-ray flux, with an average flux of \( \Phi(> 100 \text{ MeV}) = 15 \times 10^{-8} \text{ ph cm}^{-2} \text{s}^{-1} \) between 1991 and 1995, and a maximum detected flux of \( \Phi(> 100 \text{ MeV}) = 80 \times 10^{-8} \text{ ph cm}^{-2} \text{s}^{-1} \) in 1997. The EGRET average spectrum has a power-law shape with photon index \( \Gamma = 2.8 \pm 0.1 \), but variations of the spectral slope have been observed, with the spectrum hardening while the source brightened. A flux variability by a factor of 4 within one week is the most extreme behaviour observed for 3C 273 at...
3.2. Fermi/LAT data analysis

The Fermi satellite, launched in June 2008, carries two instruments able to observe the gamma-ray sky: the Large Area Telescope (LAT), a pair conversion gamma-ray telescope sensitive to gamma rays from 30 MeV to 200 GeV [14]; and the GLAST Burst Monitor (GBM), observing the sky in the 8 keV to 30 MeV energy range [13]. The main instrument LAT is 10 times more sensitive than its predecessors CGRO/EGRET and AGILE/GRID and, thanks to its large field of view of 2.4 sr, it can scan the full sky every 3 hours. A ready after the first 3 months of observations, the LAT had detected 205 objects with high-con dence, of which 106 are AGN [15], including 3C 273.

We analysed the Fermi/LAT data collected during the first 10 months of observations, between August 10, 2008 and October 19, 2009. We used a maximum likelihood algorithm. For a region of interest (ROI) of 15 around 3C 273, a model containing the isotropic and Galactic diffuse background models (as given by default) and all the sources in the catalog was fit to the data. For the ROI and data analysed, beside 3C 273 two additional sources were considered: the blazar 3C 279 and the unidentified source at RA = 189.9, DEC = 4.7.

During the first year of observations, AGILE/GRID has detected 3C 273 with an average flux of \( F(>100\text{MeV}) = 24 \times 10^{8} \text{ph cm}^{-2} \text{s}^{-1} \), consistent with EGRET measurements [14]. During the multiwavelength campaign of December (January 2008), the source was detected only during the second week of observations at a flux of \( F(>100\text{MeV}) = 34 \times 10^{8} \text{ph cm}^{-2} \text{s}^{-1} \). The hard X-ray to gamma-ray emission is modeled as a superposition of a few disk photons, and the variability of this high-energy component is consistent with an acceleration phase of the electron distribution that moves the inverse Compton peak to higher energies.

### 3.3. Fermi/LAT preliminary results

Figure 5 shows the results obtained during the first 15 months of observations. In the selected time intervals analysed, 3C 273 was always detected with TS \( > 5 \). Since the launch of Fermi, 3C 273 has undergone several episodes of very intense gamma-ray activity. The average flux above 100 MeV, \( F(>100\text{MeV}) = 1.4 \times 10^{6} \text{ph cm}^{-2} \text{s}^{-1} \), is significantly larger than the historical median values of EGRET, with a peak flux of \( F(>100\text{MeV}) = 5 \times 10^{6} \text{ph cm}^{-2} \text{s}^{-1} \) detected during a large flare in September 2009. The amplitude of the variations, \( F_{\text{var}} \) (quantified through the fractional variability amplitude; see [8] for more detail), measured by Fermi is consistent with the EGRET one at

4. The inverse Compton peak

Gamma-ray observations of 3C 273 are essential to constrain the overall shape of the inverse Compton branch and to better understand the connection between the jet emission in different energy domains. The most recent radio to gamma-ray campaigns carried out on this object, together with the numerous ones performed in the past, provide a large set of data to model the spectral energy distribution (SED) during several epochs and with different integration times (the average SED in Fig. 3).

Multiwavelength campaigns performed during EGRET observations could not discriminate between the most common models used to describe the high-energy emission of blazars [9]. A different variability behaviour below and above 30 MeV suggested that two different mechanisms are responsible for the emission in the MeV and in the EGRET domain, with...
the latter one being most likely produced by inverse Compton scattering of accretion disc photons [3]. On the other hand, the diffuse variability of the hard X-rays and gamma-rays detected by INTEGRAL and AGILE has been explained by a single external Compton component shifted toward higher energies following an acceleration of the electron population, whereas a synchrotron self-Compton contribution is evident at lower energies [14].

Several multiwavelength monitoring programs are ongoing to follow the evolution of 3C 273 and many other gamma-ray sources. The preliminary results presented during the 2009 Fermi Symposium for 3C 273 indicate that there is a correlation between the gamma-ray arcing states and the brightening of the VLB core, with gamma-ray sources following the ejection of a superluminal knot by up to 70 days [15]. This would indicate that the gamma-ray high states are related to a disturbance crossing the mJ13.5m eter-jet core. An increase of the radio emission at 15 GHz has been observed quasi-simultaneously to the large September 2009 gamma-ray arc, and the optical arc started also to increase in July/August 2009, but no data were available at the time of the gamma-ray arc [19]. In addition, a correlation between the small gamma-ray arc of April 2009 and the optical emission is clearly detected [13].

As the arcing optical emission of 3C 273 is believed to be synchrotron emission related to the millimeter jet, a gamma-ray/optical correlation would support the origin of the high-energy emission in the millimeter jet and could indicate that the same electron population is responsible for both emissions through synchrotron and inverse Compton processes. On the other hand, we found the hard X-ray emission to be related rather to another optical component, varying on longer time scales, and produced as synchrotron emission further away from the millimeter jet [6]. Therefore, this would point to a diffuse origin of the hard X-ray and gamma-ray emissions.

5. Conclusions

Thanks to its large field of view and its unprecedented sensitivity above 100 MeV, the LAT instrument is providing us with long-term, well-sampled light curves and spectral information for a large number of AGN [14, 15, 21]. Among them, 3C 273 is a bright quasar extensively observed at all wavelengths and showing a particularly intense gamma-ray activity since the launch of Fermi. This source was detected during the first 15 months of observations with an average flux of \(F(>100\text{MeV}) = 1.4 \times 10^{-6} \text{ph cm}^{-2} \text{s}^{-1}\), corresponding to an average luminosity of \(L_\gamma = 3 \times 10^{44} \text{erg s}^{-1}\), and an average photon index of \(\Gamma = 2.78 \pm 0.03\). In September 2009, during a very bright phase reaching a peak flux of \(F(>100\text{MeV}) = 5.8 \times 10^{-6} \text{ph cm}^{-2} \text{s}^{-1}\), the hint of a spectral hardening accompanied the brightening of the source, possibly indicating a shift of the inverse Compton peak from 1(10 MeV) to higher energies.

When looking at the multi-band behaviour, the amplitude of the variations seems to constantly increase from the X-rays up to the gamma-ray band, with the MeV - GeV range showing the largest variations along the electron magnetic spectrum. On one side the correlation of the gamma-ray spectra with the millimeter jet and with the optical arcing component [13, 19], and on the other side the lack of correlation between the hard...
X-rays and the millimeter emission might indicate a different origin of the high-energy emission below and above the peak of the inverse Compton hump.

An extensive correlation study and an accurate modeling of the broad band spectral energy distribution during several epochs [20,22] will allow to shed more light on the origin of the gamma-rays in 3C 273 and their connection to the emission in other bands.
