1. INTRODUCTION

Following the demonstration that self-consistent equilibra could be constructed for triaxial galaxy models (Schwarzschild 1979, 1982), observational evidence gradually accumulated for non-axisymmetry on large (kilo-parsec) scales in early-type galaxies (Franx et al. 1991, Statler et al. 2004, Cappellari et al. 2007). On smaller scales, imaging of the centers of galaxies also revealed a wealth of features in the stellar distribution that are not consistent with axisymmetry, including bars, bars-within-bars, and nuclear spirals (Shaw et al. 1993, Erwin & Sparke 2002, Seth et al. 2008). In the nuclei of low-luminosity galaxies, the non-axisymmetric features may be recent or recurring, associated with ongoing star formation; in luminous elliptical galaxies, central relaxation times are so long that triaxiality, once present, could persist for the age of the universe.

In a triaxial nucleus, torques from the stellar potential can induce gradual changes in the eccentricities of stellar orbits, allowing stars to find their way into the central BH. Gravitational two-body scattering also drives stars into the central BH, but only on a time scale of order the central relaxation time, which can be very long, particularly in the most luminous galaxies. Simple arguments suggest that the feeding of stars to the central BHs in many galaxies is likely to be dominated by large-scale torques rather than by two-body relaxation (e.g. Merritt & Poon 2004).

This paper discusses the character of orbits near a supermassive BH in a triaxial nucleus. The emphasis is on low-angular-momentum, or “centrophilic,” orbits, the orbits that come closest to the BH. Self-consistent modeling (Poon & Merritt 2004) reveals that a large fraction of the orbits in triaxial BH nuclei can be centrophilic.

Within the BH influence sphere, orbits are nearly Keplerian, and the force from the distributed mass can be treated as a small perturbation which causes the orbital elements (inclination, eccentricity) to change gradually with time. A standard way to deal with such motion is via orbit averaging (e.g. Sanders & Verhulst 1985), i.e., averaging the equations of motion over the short time scale associated with the unperturbed Keplerian motion. The result is a set of equations describing the slow evolution of the remaining orbital elements due to the perturbing forces. This approach was followed by Sridhar & Touma (1999) for motion in an axially-symmetric nucleus containing a massive BH, and by Sambhus & Sridhar (2000) for motion in a constant-density triaxial nucleus.

In their discussion of motion in triaxial nuclei, Sambhus & Sridhar (2000) passed over one important class of orbit: the centrophilic orbits, i.e., orbits that pass arbitrarily close to the BH. Examples of centrophilic orbits include the two-dimensional “lens” orbits (Sridhar & Touma 1997, 1999) and the three-dimensional “pyramids” (Merritt & Valuri 1999, Poon & Merritt 2001). Centrophilic orbits are expected to dominate the supply of stars and stellar remnants to a supermassive BH (e.g. Merritt & Poon 2004) and are the focus of the current paper.

The paper is organized as follows. In §2 we present a
model for the gravitational potential of a triaxial nuclear star cluster, which is more general than that studied in Sambhus & Sridhar (2000), but which has many of the same dynamical features. Then in §3 we write down the orbit-averaged equations of motion, and in §4 present a detailed analytical study of their solutions, with emphasis on the case where the triaxiality is weak and the eccentricity large. In this limiting case, the averaged equations of motion turn out to be fully integrable. In §5 we derive the equations that describe the rate of capture of stars on pyramid orbits by the BH. Comparison of orbit-averaged treatment with real-space motion is made in §6 to test the applicability of the former. In §7 we consider the effect of general relativity on the motion, which imposes an effective upper limit on the eccentricity. §8 discusses the connection with resonant relaxation: we argue that a similar upper limit to the eccentricity should characterize orbital evolution in the case of resonant relaxation. Finally, in §9 we make some quantitative estimates of the importance of pyramid orbits for capture of stars in galactic nuclei. §10 sums up.

2. MODEL FOR THE NUCLEAR STAR CLUSTER

Consider a nucleus consisting of a BH, a spherical star cluster, and an additional triaxial component. An expression for the gravitational potential that includes the three components is

\[ \Phi(r) = -\frac{GM\bullet}{r} + \Phi_s \left( \frac{r}{r_0} \right)^{2-\gamma} + 2\pi G \rho_t \left( T_x x^2 + T_y y^2 + T_z z^2 \right). \]

The second term on the right hand side is the potential of a spherical star cluster with density \( \rho(r) = \rho_s (r/r_0)^{-\gamma} \); the coefficient \( \Phi_s \) is given by

\[ \Phi_s = \frac{4\pi G}{(3 - \gamma)(2 - \gamma)} \rho_s r_0^2. \]

The scale radius \( r_0 \) may be chosen arbitrarily but it is convenient to set \( r_0 = r_{\text{infl}} \), with \( r_{\text{infl}} \) the radius at which the enclosed stellar mass is twice \( M\bullet \):

\[ r_{\text{infl}} = \left( \frac{3 - \gamma}{2\pi} \right)^{1/3} M\bullet. \]

The third term is the potential of a homogeneous triaxial ellipsoid of density \( \rho_t \); this term can also be interpreted as a first approximation to the potential of a more general, inhomogeneous triaxial component. In the former case, the dimensionless coefficients \( (T_x, T_y, T_z) \) are expressible in terms of the axis ratios \( (p, q) \) of the ellipsoid via elliptic integrals. (Chandrasekhar 1969). The \( x(z) \) axes are assumed to be the long(short) axes of the triaxial figure; this implies \( T_x \leq T_y \leq T_z \). In what follows we will generally assume \( \rho_t \ll \rho_s (r_0) \), i.e. that the triaxial bulge has a low density compared with that of the spherical cusp at \( r = r_{\text{infl}} \).

3. ORBIT-AVERAGED EQUATIONS

Within the BH influence sphere, orbits are nearly Keplerian\(^1\) and the force from the distributed mass can be treated as a small perturbation which causes the elements of the orbit (inclination, eccentricity etc.) to change gradually with time. A standard way to deal with such motion (e.g. Sanders & Verheijen 1995) is to average the equations over the coordinate executing the most rapid variation, e.g., the radius. The result is a set of equations describing the slow evolution of the remaining variables due to the perturbing forces.

We begin by transforming from Cartesian coordinates to action-angle variables in the Kepler problem. Following Sridhar & Touma (1999) and Sambhus & Sridhar (2000), we adopt the Delaunay variables (e.g. Goldstein et al. 2002) to describe the unper- turbated motion.

Let \( a \) be the semi-major axis of the Keplerian orbit. The Delaunay action variables are the radial action \( I = (GM\bullet a)^{1/2} \), the angular momentum \( L \), and the projection of \( L \) onto the \( z \) axis \( L_z \). The conjugate angle variables are the mean anomaly \( w \), the argument of the periastron \( \varpi \), and the longitude of the ascending node \( \Omega \).

In the Keplerian case, five of these are constants; the exception is \( w \) which increases linearly with time at a rate

\[ \nu_r = (GM\bullet)^2/I^3. \]

In terms of the new variables, the Hamiltonian is

\[ \mathcal{H} = -\frac{1}{2} \left( \frac{GM\bullet}{I} \right)^2 + \Phi_p(I, L, L_z, w, \varpi, \Omega); \]

the first term is the Keplerian contribution and \( \Phi_p \), the “perturbing potential”, contains the contributions from the spherical and triaxial components of the distributed mass. This transformation is completely general if we interpret the new variables as instantaneous (osculating) orbital elements. However if we assume that the perturbing potential is small compared with the point-mass potential, the rates of change of these variables (again with the exception of \( w \)) will be small compared with the radial frequency \( \nu_r \), and the new variables can be regarded as approximate orbital elements that change little over a radial period \( P = 2\pi/\nu_r \). Accordingly, we average the Hamiltonian over the fast angle \( w \):

\[ \overline{\mathcal{H}} = -\frac{1}{2} \left( \frac{GM\bullet}{I} \right)^2 + \overline{\Phi}_p, \]

\[ \overline{\Phi}_p \equiv \oint \frac{dw}{2\pi} \Phi = \frac{1}{2\pi} \int_0^{2\pi} dE (1 - e \cos E) \Phi_p(r). \]

The final term replaces the mean anomaly \( w \) by the eccentric anomaly \( E \), where \( r = a(1 - e \cos E) \) and the eccentricity is \( e = \sqrt{1 - L^2/I^2} \). After the averaging, \( \overline{\mathcal{H}} \) is independent of \( w \), and \( I \) is conserved, as is the semi-major axis \( a \). We are left with four variables and with \( \overline{\Phi}_p \) as the effective Hamiltonian of the system.

The spherically symmetric part of \( \overline{\Phi}_p \) is

\[ \overline{\Phi}_s = F_{\gamma}(e) \Phi_s \left( \frac{a}{r_0} \right)^{2-\gamma}, \]

\[ F_{\gamma}(e) \equiv 2F_1 \left( \left[ -\frac{3 - \gamma}{2}, -\frac{2 - \gamma}{2} \right], [1], e^2 \right). \]
A good approximation to $F_y(e)$ is

$$F_y(e) \approx 1 + \alpha e^2, \quad \alpha = \frac{2^{\frac{3}{2}} - \left(\frac{5}{2} - \gamma\right)}{\sqrt{\pi} \Gamma(4 - \gamma)} - 1 \quad (7)$$

which is exact for $\gamma = 0$ and $\gamma = 1$; for $0 \leq \gamma < 2$, $0 < \alpha \leq 3/2$. When $\gamma > 1$ and $e$ is close to 1, a better approximation is

$$F_y(e) \approx 1 + \alpha + \alpha'(e^2 - 1), \quad \alpha' = \frac{2^{\frac{3}{2}} - \left(\frac{5}{2} - \gamma\right)}{\sqrt{\pi} \Gamma(3 - \gamma)} \quad (8)$$

We adopt the latter expression in what follows. Good approximations are

$$\alpha \approx \frac{3}{2} - \frac{29}{60} \gamma^2 + \frac{7}{20} \gamma^2 - \frac{1}{30} \gamma^3, \quad \alpha' \approx \frac{3}{2} - \frac{29}{60} \gamma^2 + \frac{11}{20} \gamma^2 - \frac{1}{10} \gamma^3. \quad (9a)$$

$$\alpha \approx \frac{3}{2} - \frac{29}{60} \gamma^2 + \frac{7}{20} \gamma^2 - \frac{1}{30} \gamma^3, \quad (9b)$$

Similar expressions can be found in Ivanov, Polnarev & Saka (2005) and Polyachenko, Polyachenko & Shukhman (2007).

Expressions for the orbit-averaged triaxial harmonic potential (excluding the spherical component) are derived in Sambhus & Sridhar (2000). Adopting their notation, the orbit-averaged potential in our case becomes

$$\bar{H}_b = \Phi_b \left(\frac{a}{r_0}\right)^{2-\gamma} (1 + \alpha - \alpha' \ell^2) + 2\pi G\rho_T a^2 \times (10a)$$

$$\times \left[\frac{5}{2} - \frac{3}{2} \ell^2 + \epsilon_b^{(i)} H_b(\ell, \ell_z, \omega, \Omega) + \epsilon_c^{(i)} H_c(\ell, \ell_z, \omega)\right]$$

$$H_b = \frac{1}{4} \left[ 5 - 4\ell^2 \right] (c_\omega s_0 + c_\Omega s_\Omega)^2$$

$$+ \ell^2 (s_\omega s_0 - c_\Omega c_\Omega)^2, \quad (10b)$$

$$H_c = \frac{1}{4} \left[ 1 - c_\omega^2 \right] [5 - 3\ell^2 - 5(1 - \ell^2) c_{2\omega}], \quad (10c)$$

$$\epsilon_b^{(i)} \equiv T_{b/2} - T_{1/2}, \quad \epsilon_c^{(i)} \equiv T_{c/2} - T_{1/2}. \quad (10d)$$

The shorthand $s_\omega, c_\omega$ has been used for $\sin x, \cos x$. We have defined the dimensionless variables $\ell = L/I$ and $\ell_z = L_{z/2}$, both of which vary from 0 to 1; the orbital inclination $i$ is given by $\cos i \equiv \ell_z/\ell$ and the eccentricity by $\epsilon^2 = 1 - \ell^2$.

The first term in equation (10a), which arises from the spherically-symmetric case, does not depend on the angular variables, and has the same dependence on $\ell^2$ as the corresponding term in the harmonic triaxial potential. So we can sum up the coefficients at $\ell^2$ and renormalize the triaxial coefficients $\epsilon_b, c$ to obtain the same functional form of the Hamiltonian as in the purely harmonic case. Dropping an unnecessary constant term (depending only on $a$) and defining a dimensionless time $\tau = \nu_p \ell$, where $\nu_p$ is characteristic rate of precession,

$$\nu_p \equiv 2\pi G\rho_T a^2 (1 + A)/I, \quad (11)$$

$$A \equiv \frac{4\alpha'}{3(3-\gamma)(2-\gamma)I_T} \rho_T \left(\frac{a}{r_0}\right)^{-\gamma}, \quad (12)$$

we obtain the dimensionless Hamiltonian and the equations of motion describing the perturbed motion:

$$H \equiv \frac{\bar{H}_b}{\nu_p} = -\frac{3}{2} \ell^2 + \epsilon_b H_b + \epsilon_c H_c, \quad (13a)$$

$$\frac{d\ell}{dr} = -\frac{\partial H}{\partial \ell}, \quad \frac{d\ell_z}{dr} = -\frac{\partial H}{\partial \ell_z}, \quad \frac{d\omega}{dr} = -\frac{\partial H}{\partial \omega}, \quad \frac{d\Omega}{dr} = -\frac{\partial H}{\partial \Omega}. \quad (13b)$$

The renormalized triaxiality coefficients are $\epsilon_{b,c} \equiv \epsilon_{b,c}^{(i)}/(1 + A)$.

If there were no spherical component ($A = 0$), this would reduce to the purely harmonic triaxial case studied by Sambhus & Sridhar (2000). Adding the spherically symmetric cusp increases the rate of periastron precession, while at the same time reducing the relative amplitude of the triaxial terms; otherwise the form of the Hamiltonian is essentially unchanged.

A more transparent expression for the precession frequency $\nu_p$ is

$$\nu_p = \nu_r \frac{M_s(a)}{M_*} \frac{37\nu_s}{M_*} \frac{2\alpha'}{M_*} \frac{\nu_s}{M_*} \frac{3(2-\gamma)}{M_*} \quad (14a)$$

$$M_s(a) \equiv \frac{4\pi}{3} a^3 \rho_s, \quad M_s(a) \equiv \frac{4\pi}{3} a^3 \rho_s \left(\frac{a}{r_0}\right)^{-\gamma} \quad (14b)$$

where $M(a)$ denotes the mass enclosed within radius $r = a$. From equation (13a), the precession rate of an orbit in the spherical cluster is $\nu_s \equiv |d\varpi/dr| = 3\nu_s = 3\nu_I = \ell^2 \nu_p$. Near the BH influence radius, it is clear that $\nu_p \approx \nu_r$; hence the orbit-averaged treatment, which assumes only one “fast” variable, is likely to break down at this radius.

We note that $\nu_s \rightarrow 0$ as $a \rightarrow 1$. For the very eccentric orbits that are the focus of this paper, the rate of precession is much lower than for a typical, non-eccentric orbit of the same energy. This will turn out to be important, since the slow precession allows torques from the triaxial part of the potential to build up.

4. ORBITAL STRUCTURE OF THE MODEL POTENTIAL

4.1. General remarks

The orbit-averaged Hamiltonian (15a) describes a dynamical system of two degrees of freedom. The trajectories must be obtained by numerical integration of the equations of motion (13b). We begin by making some qualitative points about the nature of the solutions.

In the absence of the triaxial terms in equation (15a), the effect of the distributed mass is to rotate the periastron angle $\varpi$ in a fixed plane; this steadily rotating elliptic orbit fills an annulus. The addition of a weak triaxial perturbation changes the rate of in-plane precession slightly, and also causes the orbital plane itself to change, as described by the last two terms in equation (13b).

In general, two angular variables $\varpi$ and $\Omega$ can either librate around fixed points or circulate, giving rise to four basic families of orbits (Figure 1). Solutions to the equations of motion that are characterized by circulation in both $\varpi$ and $\Omega$ correspond to tube orbits about the short axis (SAT). Motion that circulates in $\varpi$ but librates in $\Omega$ corresponds to tube orbits about the long axis (SET). Two such examples are shown in Figures 1(a–b). 

2 Equation (12) of Sambhus & Sridhar (2000) for $\ell$ lacks a minus sign in front of the first term.
axis (LAT). Both types of orbit are qualitatively similar to the tube orbits that are generic to the triaxial geometry \cite{Schwarzschild1979}. A subclass of the SAT orbits corresponds to motion that circulates in $\Omega$ and librates in $\varpi$ \cite{SambhusSridhar2000, PoonMerritt2001}. These orbits resemble cones, or saucers; similar orbits exist also at $r \gg r_{\text{infl}}$ in oblate or nearly oblate potentials \cite{Richstone1982, LeesSchwarzschild1992}.

If the degree of triaxiality is small ($\epsilon_{b,c} \ll 1$), then as noted above, the dominant effect of the distributed mass is simply to induce a periapse shift, at a rate $\nu_{\varpi} \equiv d\varpi/d\tau = -3\ell$. If the additional mass is much less than the mass of the BH, then on short time scales (comparable to the radial period $\nu_{r}^{-1}$) the orbit resembles a nearly closed ellipse. On intermediate time scales (of order the precession time $\nu_{\varpi}^{-1}$), a steadily-rotating elliptic orbit fills an annulus in a fixed plane. On still longer time scales $\nu_{\Omega}^{-1}$, the orbital plane itself changes due to the torques from the triaxial potential. Similar considerations give rise to the concept of vector resonant relaxation \cite{RauchTremaine1996}.

The foregoing description is valid as long as the angular momentum is not too low. Since the precession rate is proportional to $\ell$, for sufficiently low $\ell$ the intermedi-
ate and long time scales become comparable (Figure 2). As a result, the triaxial torques can produce substantial changes in ℓ (i.e. the eccentricity) on a precession time scale via the first term in (13b), and the circulation in w can change to libration. This is the origin of the pyramid orbits, which are unique to the triaxial geometry (Merritt & Valluri 1999).

4.2. Pyramid orbits

Of the four orbit families discussed above, the first three were treated, in the orbit-averaged approximation, by Sambhus & Sridhar (2000). The fourth class of orbits, the pyramids, are three-dimensional analogs of the two-dimensional “lens” orbits discussed by Sridhar & Touma (1995), also in the context of the orbit-averaged equations. An important property of the pyramid orbits is that ℓ can come arbitrarily close to zero (Poon & Merritt 2001) and Merritt & Poon (2004). This makes the pyramids natural candidates for providing matter to BHs at the centers of galaxies.

Pyramid orbits can be treated analytically if the following two additional approximations are made: (1) the angular momentum is assumed to be small, ℓ2 ≪ 1; (2) the triaxial component of the potential is assumed to be small compared with the spherical component, i.e. εb,εc ≪ 1. As shown below, these two conditions are consistent, in the sense that ℓ2 max ≃ εb,εc for pyramid orbits.

Removing the second-order terms in εb,εc and in ℓ2 from the orbit-averaged Hamiltonian (13a), we find

\[ H = -\frac{3}{2}\ell^2 + \frac{5}{2} [\epsilon_c(1 - \epsilon_c^2)\ell_w^2 + \epsilon_b(\ell_w s_\Omega + c_i s_w c_{\Omega 1})^2] \] (15)

where again εc ≡ cos i = ℓz/ℓ.

Because an orbit described by (15) is essentially a precessing rod, one expects the important variables to be the two that describe the orientation of the rod, and its eccentricity. This argument lead us to search for exact solutions to the equations of motion in terms of the Laplace-Runge-Lenz vector, or its dimensionless counterpart, the eccentricity vector, which point in the direction of orbital periapse.

We therefore introduced new variables e_x, e_y and e_z:

\[ e_x = \cos w \cos \Omega - \sin w \sin \Omega \cos i \] (16a)
\[ e_y = \sin w \cos i \cos \Omega + \cos w \sin \Omega \] (16b)
\[ e_z = \sin w \sin i \] (16c)

which correspond to components of a unit vector in the direction of the eccentricity vector. Of these, only two are independent, since e_x^2 + e_y^2 + e_z^2 = 1. In terms of these variables, the Hamiltonian (15) takes on a particularly simple form:

\[ H = -\frac{3}{2}\ell^2 + \frac{5}{2} [\epsilon_c - \epsilon_c e_z^2 - (\epsilon_c - \epsilon_b) e_y^2] \] (17)

As expected, the Hamiltonian depends on only three variables: e_x and e_y, which describe the orientation of the orbit’s major axis, and the eccentricity ℓ. To find the equations of motion, we must switch to a Lagrangian formalism. Taking the first time derivatives of equations (17) and using equations (13b), we find

\[ \dot{e}_x = 3\ell (\sin w \cos \Omega + \cos w \sin \Omega \cos i), \quad \dot{e}_y = 3\ell (\sin w \sin \Omega - \cos w \cos \Omega \cos i) \] (18a)

where \( \dot{e}_x \equiv de_x/d\tau \) etc. Taking second time derivatives, the variables describing the orientation and eccentricity of the orbit drop out, as desired, and the equations of motion for e_x and e_y can be expressed purely in terms of e_x and e_y:

\[ \ddot{e}_x = -e_x \left( H + 3\ell^2 \right) \] (19a)
\[ = -e_x \left[ 30\epsilon_c - 6H - 30\epsilon_c e_x^2 - 30(\epsilon_c - \epsilon_b) e_y^2 \right], \quad \ddot{e}_y = -e_y \left( H + 3\ell^2 - \frac{5}{2} \epsilon_b \right) \] (19b)
\[ = -e_y \left[ 30\epsilon_c - 6H - 15\epsilon_b - 30\epsilon_c e_x^2 - 30(\epsilon_c - \epsilon_b) e_y^2 \right]. \]

From equations (18), (\( \dot{e}_x, \dot{e}_y \)) = 0 implies ℓ = 0, i.e. the eccentricity reaches one at the “corners” of the orbit. These define the base of the pyramid. Defining (e_x0, e_y0) to be the values of (e_x, e_y) when this occurs, vthen Hamiltonian has numerical value

\[ H = \frac{5}{2} e_c \left[ e_c e_x^2 + (e_c - \epsilon_b) e_y^2 \right]. \] (20)

Equations (19) have the form of coupled, nonlinear oscillators. Given solutions to these equations, the time dependence of the additional variables (ℓ, ε_x, ε_y, w) follows immediately from equations (16) and (18):

\[ \ell^2 = \frac{e_x^2 + e_y^2 - (\dot{e_x} e_y - e_x \dot{e_y})^2}{9(1 - e_x^2 - e_y^2)} = \frac{1}{9}(e_x^2 + e_y^2 + e_z^2), \]
\[ \dot{\ell}_x = (\dot{e}_x e_y - e_x \dot{e}_y)/3, \]
\[ \sin^2 w = \frac{1 - e_x^2 - e_y^2}{1 - \ell_x^2/\ell^2} = \frac{e_z^2}{1 - e_x^2 - e_y^2}, \]

and a quite lengthy expression for Ω which we choose not to reproduce here.

In the limit of small amplitudes, (e_x, e_y) ≪ 1 (which corresponds to \( H \approx \frac{3}{2} \epsilon_c \)), the oscillations are harmonic and uncoupled, with dimensionless frequencies

\[ \nu_{x0} \equiv \sqrt{15} \epsilon_c, \quad \nu_{y0} \equiv \sqrt{15} (\epsilon_c - \epsilon_b). \] (22)

The apoapse traces out a 2d Lissajous figure in the plane perpendicular to the short axis of the triaxial figure. This is the base of the pyramid (e.g. Merritt & Valluri 1999, Figure 11). The solutions in this limiting case are

\[ e_x(\tau) = e_{x0} \cos(\nu_{x0} \tau + \phi_x), \]
\[ e_y(\tau) = e_{y0} \cos(\nu_{y0} \tau + \phi_y), \]
\[ \ell^2(\tau) = \ell_{x0}^2 \sin^2(\nu_{x0} \tau + \phi_x) + \ell_{y0}^2 \sin^2(\nu_{y0} \tau + \phi_y) \]

where \( \phi_x, \phi_y \) are arbitrary constants and

\[ \ell_{x0} = \nu_{x0} e_{x0}/3, \quad \ell_{y0} = \nu_{y0} e_{y0}/3. \] (24)

Figure 3 plots an example.

Equations (23) describe integrable motion. Remarkably, it turns out that the more general (anharmonic, coupled) equations of motion (19) are integrable as well.
The first integral is $H$; an equivalent, but nonnegative, integral is $U$ where

$$U \equiv 15\epsilon_x - 6H = \nu_{x0}^2\epsilon_x^2 + \nu_{y0}^2\epsilon_y^2 + (\epsilon_x^2 + \epsilon_y^2 + \epsilon_z^2). \quad (25)$$

The second integral is obtained after multiplying the first of equations (19) by $15\epsilon_x\dot{e}_x$, the second by $15(\epsilon_x - e_0)\dot{e}_y$, and adding them to obtain a complete differential. The integral $W$ is then

$$W = \nu_{x0}^2(\epsilon_x^2 + \epsilon_y^2 - \nu_{y0}^2\epsilon_x^4) + \nu_{y0}^2(\epsilon_y^2 + \epsilon_y^2 - \nu_{y0}^2\epsilon_y^4) - 2\nu_{x0}^2\nu_{y0}^2\epsilon_x^2\epsilon_y^2,$$

$$\nu_x^2 \equiv U + \nu_{x0}^2, \quad \nu_y^2 \equiv U + \nu_{y0}^2. \quad (26a)$$

The existence of two integrals $(U, W)$, for a system with two degrees of freedom, demonstrates regularity of the motion.

Regular motion can always be expressed in terms of action-angle variables. The period of the motion, in each degree of freedom, is then given simply by the time for the corresponding angle variable to increase by $2\pi$. We were unable to derive analytic expressions for the action-angle variables corresponding to the two-dimensional motion described by equations (19). However the periods of oscillation of the planar orbits $(e_x = 0 \text{ or } e_y = 0)$ described by these equations are easily shown to be

$$\nu_{x0}P(e_{x0}) = 4K(\epsilon_{x0}) \quad (e_x = 0),$$

$$\nu_{y0}P(e_{y0}) = 4K(\epsilon_{y0}) \quad (e_x = 0) \quad (27)$$

where $K(\alpha)$ is the complete elliptic integral:

$$K(\alpha) = \int_0^{\pi/2} (1 - \alpha \sin^2 x)^{-1/2} dx.$$
orbits. Lower (dark blue) line (a), equation (29); upper (red) curve (d), equation (34); green line (c), equation (30); light blue line (b), equation (31). Red points, equation (29); blue points, equation (32). Plotted for \( \epsilon_x = 0.002, \epsilon_z = 0.008 \).

4.3. The complete phase space of eccentric orbits

While our focus is on the pyramid orbits, the low-angular-momentum Hamiltonian \( 15 \) also supports orbits from other families. In this section, we complete the discussion of the phase space described by equation (15), by delineating the regions in the \( U - W \) plane that are occupied by each of the four orbit families (Figure 4).

Pyramids and LATs both resemble distorted rectangles in the \( \epsilon_x, \epsilon_y \) plane. The corner points of this region correspond to \( \dot{\epsilon}_x = \dot{\epsilon}_y = 0 \). Evaluating the two integrals at a corner (denoted by the subscript 0) gives

\[
U = \nu^2_{x0} \epsilon^2_{x0} + \nu^2_{y0} \epsilon^2_{y0} + \epsilon^2_{z0},
\]

(28a)

\[
W = \nu^4_{x0} \epsilon^2_{x0} + \nu^4_{y0} \epsilon^2_{y0} + (U - \epsilon^2_{z0}) \epsilon^2_{z0}.
\]

(28b)

The difference between pyramids and LATs arises from the last term: corner points of pyramid orbits correspond to \( \ell^2 = 0 \) and hence (from (21a)) to \( \dot{\epsilon}_{z0} = 0 \). For LATs the condition is, conversely, \( \epsilon^2_{z0} > 0 \), and \( \dot{\epsilon}_{z0} = 0 \) (hence \( \epsilon^2_{y0} = 1 - \epsilon^2_{z0} \)). Analyzing these expressions, we find that for pyramids and LATs the lower and upper boundaries for \( W \) given \( U \) are

\[
W = \nu^2_{x0} U,
\]

(29)

\[
W = \nu^2_{y0} U,
\]

(30)

and the boundary between pyramids and LATs is given by

\[
W = (\nu^2_{x0} + \nu^2_{y0}) U - \nu^2_{x0} \nu^2_{y0}.
\]

(31)

Pyramids lie above and to the left of this line in the \( U - W \) plane, while LATs are below and to the right. The intersection of this line with (29) and (30) occurs at the points

\[
U = \nu^2_{y0}, \quad W = \nu^4_{y0},
\]

(32a)

\[
U = \nu^2_{x0}, \quad W = \nu^4_{x0}.
\]

(32b)

These points constitute the leftmost bound for LATs and the rightmost bound for pyramids respectively.

Short-axis tubes and saucers resemble distorted rectangular regions in the \( \epsilon_x, \epsilon_z \) plane. Again, the corner points (with subscript 0) are defined to have \( \dot{\epsilon}_x = \dot{\epsilon}_z = 0 \) and \( \epsilon_y = 0 \), with \( \epsilon^2_{y0} > 0 \), and therefore

\[
U = \nu^2_{x0} \epsilon^2_{x0} + \epsilon^2_{y0},
\]

(33a)

\[
W = \nu^2_{x0} U + (\nu^2_{x0} \epsilon^2_{x0} + \nu^2_{y0} - \nu^2_{x0}) \epsilon^2_{y0}.
\]

(33b)

Both these families have \( W \geq \epsilon_y U \), i.e., lie above the line (33). SAT orbits intersect the plane \( \epsilon_z = 0 \), so we can set \( \epsilon_{z0} = 1 \) in (33). (Alternatively, for SATs, both angles circulate, so we can set \( \omega = \Omega = 0 \), which again gives \( \epsilon_z = 1 \)). We then find that SATs lie below the line (33).

On the other hand, saucers never reach \( \epsilon_z = 0 \) (since for them \( \sin^2 \omega > 0 \)), so that they lie above the line (33). To obtain the upper limit for \( W \) at fixed \( U \), we substitute \( \epsilon^2_{y0} \) from the first equation in (33) in the second, and then seek a maximum of \( W \) with respect to \( \epsilon_{x0} \) at fixed \( U \). This gives

\[
W = \nu^2_{x0} U + (U + \nu^2_{y0} - \nu^2_{x0}) \nu^2_{y0} / 4.
\]

(34)

This curve intersects (30) and (31) in the points

\[
U = \nu^2_{x0} - \nu^2_{y0}, \quad W = \nu^2_{y0} U,
\]

(35a)

\[
U = \nu^2_{x0} + \nu^2_{y0}, \quad W = \nu^2_{x0} U + \nu^2_{y0},
\]

(35b)

which define the left- and rightmost bounds for the saucer region.

All these criteria are summarized in Figure 4. In particular, pyramid orbits exist in the following cases:

- for \( 0 \leq H \leq \frac{5}{2} \epsilon_b \) they coexist with LATs;
- for \( 0 \leq H \leq \frac{5}{2} (\epsilon_c - \epsilon_b) \) they coexist with SAT saucers;
- above these values they are the only population for \( H \leq \frac{5}{2} \epsilon_c \), which is the maximum allowed value of \( H \);
- below \( H < 0 \) pyramids do not exist (this is easily seen from equation (15)): since the term in square brackets is always non-negative, it is impossible to have \( \ell^2 = 0 \) when \( H < 0 \).

Figure 5 shows Poincaré surfaces of section for \( \Omega = \pi/2 \) and \( 0 < H < \frac{5}{2} \epsilon_b \). The three families of orbits are delineated.

Since \( H \) is an integral of the motion, the maximum allowed value of \( \ell^2 \) cannot exceed

\[
\ell^2_{\text{max}}(H) = \frac{5 \epsilon_c - 2H}{3 + 4 \epsilon_c - \epsilon_b} \approx \frac{1}{3} (5 \epsilon_c - 2H).
\]

(36)

The latter approximate expression is immediately seen from the simplified Hamiltonian (15), while the former comes from the exact Hamiltonian (13). However, it does not follow that an orbit with a sufficiently low instantaneous value of the angular momentum is necessarily a pyramid: both tube families can also have arbitrarily low \( \ell \). The principal distinction is that any pyramid orbit can achieve arbitrarily low \( \ell \) (that is, the lower bound is \( \ell = 0 \)), while tube orbits always have \( 0 < \ell^2 \leq \ell^2 \) (however small \( \ell^2 \) may be, it is strictly positive).
(with uniform distribution in Initial conditions were drawn randomly for 10 \( \ell \), and in low-
the full Hamiltonian (13), i.e. we no longer require
which precludes pyramid orbits. Boundaries are marked by the same
letters by the same authors.

We now return from the simplified Hamiltonian \([13]\) to
the full Hamiltonian \([13]\), i.e. we no longer require \( \epsilon \) to be small. The full Hamiltonian retains all the qualitative
properties of the simplified system but requires numerical
integration of the equations of motion\([13]\) to determine
orbit classes.

To quantify the overall fraction of pyramid orbits in a
given potential, one should uniformly sample the phase space for all four variables and determine the orbit class for each individual condition. From equation \([30]\), we can restrict ourselves to values of \( \ell^2 \leq \ell^2_{\text{max}}(0) = \frac{\omega \pi}{3+\epsilon_c-\epsilon_b} \) (but we must take care to not filter out initial conditions corresponding to \( H < 0 \)).

We calculated the proportions of the \( \ell^2_{\text{max}}\)-restricted fraction of phase space occupied by each family of orbits. Initial conditions were drawn randomly for \( 10^4 \) points (with uniform distribution in \( \ell^2 \leq [0,\ell^2_{\text{max}}] \), in \( \ell_c \in [0,\ell] \), and in \( \varpi,\Omega \in [0,\frac{\pi}{2}] \)). The proportions were found to depend very weakly on \( \epsilon_c \) if \( \epsilon_c \ll 1 \). To elucidate the dependence on \( \epsilon_b/\epsilon_c \) (the degree of triaxiality) we took 15 values in the range \( (0.001 - 0.999) \).

We found that the relative fraction \( \eta \) of pyramids among low-\( \ell \) orbits is almost independent of \( \epsilon_c \) (Figure 6):

\[
\eta \approx 0.28 \sqrt{\frac{4\epsilon_b}{\epsilon_c} \left( 1 - \frac{\epsilon_b}{\epsilon_c} \right)}.
\]  

The fraction of pyramids among all orbits is \( \bar{\eta} = \eta \ell_{\text{max}}^2(0) = \frac{\eta}{\epsilon_c} \eta \). For comparison, the left panel of Figure 6 shows the results obtained using the simplified Hamiltonian \([13]\) and the analytical classification scheme described above, while the middle panel, made for \( \epsilon_c \approx 0.1 \), shows almost the same behavior, with the addition of a small number of chaotic orbits. We note that for \( \epsilon_c \approx 1 \) the phase space becomes largely chaotic.

These estimates of the relative fraction of pyramid or-
bits are directly applicable to a galaxy with an isotropic
distribution of stars at any energy. This assumption may
not be valid, for example, in the case of induced tangen-
tial anisotropy following the merger of supermassive BHs \(\text{Merritt \& Milosavljević 2005}\).

One can ask a different question: if we know the in-
stantaneous value of an orbit’s eccentricity and orienta-
tion, what can we conclude about the orbit class? It is clear that without knowledge of the derivatives of \( e_{x,y} \) the answer will only be probabilistic. It turns out that the probability \( p \) for an orbit with “sufficiently high” eccentricity (i.e. with \( \ell^2 \leq \ell^2_{\text{max}} \)) to be a pyramid depends mostly on the \( z \) component of the eccentricity vector:

\[
p \approx 0.7 \sqrt{\frac{1}{\epsilon_c} \left( 1 - \frac{\epsilon_b}{\epsilon_c} \right)} e_z^{1.5} \tag{38}\]

(here the normalization comes from the total number of pyramids among low-\( \ell \) orbits).

That is, an orbit lying in the plane defined by the long and intermediate axes of the potential is certainly not a pyramid, and the highest probability occurs for orbits directed toward the short axis.

4.4. Large \( \ell \) limit

In the previous sections we considered the case \( \epsilon_{b,c} \ll 1 \) and \( \ell^2 \approx \epsilon_c \), which allowed a simplification leading to integrable equations.

In the opposite case, when \( \epsilon_{b,c} \ll \ell^2 \ll 1 \), the frequency of in-plane precession, \( \nu_{\text{in}} \), is much greater than the rates change of \( \Omega \) and \( i \) (Figure 2). In this limit we can carry out a second averaging of the Hamiltonian \([13]\), this time over \( \nu_{\text{in}} \). Thus

\[
\langle H \rangle = \frac{1}{2\pi} \int_0^{2\pi} H d\varpi = -\frac{3}{2} \ell^2 \tag{39}
\]

On timescales \( T \gg \nu_{\text{in}}^{-1} \) the orbit resembles an annulus that lies in the plane defined by the angles \( i \) and \( \Omega \). The only remaining equations of motion are those that describe the change in orientation of the orbital plane:

\[
\frac{d\ell^2}{dt} = -\frac{\epsilon_b}{4} (5-3\ell^2) \left( 1 - \epsilon_c^2 \right) \sin^2 \theta,
\]

\[
\frac{d\ell^2}{dt} = \frac{\epsilon_b}{2} (5-3\ell^2) \left( 1 - \epsilon_c^2 \right) \sin^2 \theta.
\]

One expects the natural variables in this case to be the components of the angular momentum:

\[
\ell_x = \ell \sin \sin \Omega, \tag{40}
\]

\[
\ell_y = \ell \sin \cos \Omega, \tag{41}
\]

\[
\ell_z = \ell \cos i
\]

and \( \ell^2_x + \ell^2_y + \ell^2_z = \ell^2 = \text{constant} \). In terms of these variables, the Hamiltonian is

\[
\langle H \rangle = \frac{3}{4} \ell^2 + \frac{5-3\ell^2}{4\ell^2} \left[ \epsilon_b (\ell_x^2 - \ell_y^2) + \epsilon_c (\ell_z^2 - \ell_x^2) \right]. \tag{42}
\]

After some algebra, one finds the equations of motion:

\[
\dot{\ell}_x = -\frac{1}{2} (\epsilon_c - \epsilon_b) (5-3\ell^2) \frac{\ell_y \ell_z}{\ell^2}, \tag{43}
\]

\[
\dot{\ell}_y = \frac{\epsilon_c}{2} (5-3\ell^2) \frac{\ell_x \ell_z}{\ell^2}, \tag{44}
\]

\[
\dot{\ell}_z = -\frac{\epsilon_b}{2} (5-3\ell^2) \frac{\ell_x \ell_y}{\ell^2}
\]

(only two of which are independent). These can be writ-
ten
\[ \frac{d\vec{\ell}}{d\tau} = T \times \vec{\ell}, \]
\[ T = \frac{5 - 3t^2}{2t^2} \left[ \frac{\epsilon_y \ell_y}{\epsilon_z \ell_z} \right]. \]
Conservation of the Hamiltonian (41) implies
\[ \epsilon_b \ell_y^2 + \epsilon_c \ell_z^2 = \text{constant} = C. \]
This is an elliptic cylinder; the axis is parallel to the \( \ell_y \)-axis, and the ellipse is elongated in the direction of the \( \ell_y \)-axis. In addition, we know that
\[ \ell_y^2 + \ell_y^2 + \ell_z^2 = \text{constant} = \ell^2 \]
which is a sphere. So, the motion lies on the intersection of a sphere with an elliptic cylinder. There are two possibilities.
1. \( \ell^2 > C/\epsilon_b \). In this case, the cylinder intersects the sphere in a deformed ring that circles the \( \ell_x \)-axis. This corresponds to a LAT orbit.
2. \( \ell^2 < C/\epsilon_b \). In this case, the locus of intersection is a deformed ring about the \( \ell_z \)-axis. This orbit is a SAT. In other words, precession of the angular momentum vector can be either short or long (not intermediate) axes of the triaxial ellipsoid.

5. CAPTURE OF PYRAMID ORBITS BY THE BH
As we have seen, pyramid orbits can attain arbitrarily low values of the dimensionless angular momentum \( \ell \). The BH tidally disrupts or captures stars with angular momentum less than a certain critical value \( \ell_c \), or in dimensionless variables – \( \ell_c = \ell_c / I(a) \). We can express \( \ell_c \) in terms of the capture radius \( r_c \), the radius at which a star is either tidally disrupted or swallowed. For BH masses greater than \( \sim 10^8 \, M_\odot \), main sequence stars avoid disruption and \( r_c \approx r_{\text{Schw}} \approx 2GM_c / \ell^2 \); for smaller \( M_c \), tidal disruption occurs outside the Schwarzschild radius; e.g. at the center of the Milky Way, \( r_c \approx 10r_{\text{Schw}} \) for solar-type stars. Defining \( r_c = \Theta r_{\text{Schw}} \) and writing \( \ell^2 \approx GM_c r_c \), then gives
\[ \ell^2 = \Theta r_{\text{Schw}} \frac{a}{10^8 M_\odot} \left( \frac{M_\star}{10^8 M_\odot} \right) \left( \frac{a}{1 \text{ pc}} \right)^{-1}. \]
We note the following property of the pyramid orbits: as long as the frequencies of \( \epsilon_x \) and \( \epsilon_y \) oscillation are incommensurate, the vector \( (\epsilon_x, \epsilon_y) \) fills densely the whole available area, which has the form of distorted rectangle. The corner points correspond to zero angular momentum, and the “drainage area” is similar to four holes in the corners of a billiard table.

Unless otherwise noted, in this section we adopt the simple harmonic oscillator (SHO) approximation to the \( (\epsilon_x, \epsilon_y) \) motion, that is, we use the simplified Hamiltonian (13) and its solutions (23): these orbits have \( \epsilon_x^2 + \epsilon_y^2 \ll 1 \) and they form a rectangle in the \( \epsilon_x \)-\( \epsilon_y \) plane, with sides \( 2\epsilon_x, 2\epsilon_y \). As long as the motion is integrable, the results for arbitrary pyramids with \( \epsilon_x, \epsilon_y \ll 1 \) will be qualitatively similar. Quantitative results may be obtained by numerical analysis and are presented near the end of this section.

Figure 7 shows a two-torus describing oscillations in \( (\epsilon_x, \epsilon_y) \) for a pyramid orbit. In the SHO approximation, solutions are given by (23). If the two frequencies \( \nu_{x0}, \nu_{y0} \) are incommensurate, the motion will fill the torus. In this case, we are free to shift the time coordinate so as to make both phase angles \( (\phi_1, \phi_2) \) zero, yielding
\[ \ell^2(\tau) = \ell_{x0}^2 \sin^2(\nu_{x0}\tau) + \ell_{y0}^2 \sin^2(\nu_{y0}\tau) \]
\[ = \ell_{x0}^2 \sin^2 \theta_1 + \ell_{y0}^2 \sin^2 \theta_2 \]
where \( \theta_1 = \nu_{x0}\tau, \theta_2 = \nu_{y0}\tau \). (In the case of exact commensurability, i.e. \( m_1

FIG. 6.—Proportions of the restricted part of phase space (defined by \( \ell^2 < \ell_{\text{max}}^2(0) \)) that are occupied by the major orbit families: LATS, pyramids, SATs, and SAT/saucers, as a function of the ratio \( \epsilon_c/\epsilon_c \). Left: analytic estimates from the simplified orbit-averaged Hamiltonian (13) for \( \epsilon_c \to 0 \); middle: orbit-averaged Hamiltonian (13) for \( \epsilon_c = 0.1 \); right: real-space integration for orbits with semimajor axis \( a = r_{\text{Schw}} \) (equal to the BH influence radius) and \( \epsilon_c = 0.1 \).
The area enclosed by this “loss ellipse” is
\[ \pi \frac{\ell^2}{\ell_{x0}\ell_{y0}}. \] (47)

There are four such regions on the torus; together, they constitute a fraction
\[ \mu = \frac{1}{\pi} \frac{\ell^2}{\ell_{x0}\ell_{y0}} \] (48)
of the torus.

Stars move in the \((\chi, \psi)\) plane along lines with slope \(\tan \alpha = \nu_{y0}/\nu_{x0}\), at an angular rate of \(\sqrt{\nu_{x0}^2 + \nu_{y0}^2}\). Since periapse passages occur only once per radial period, a star will move a finite step in the phase plane between encounters with the BH. The dimensionless time between successive periapse passages is \(\Delta t = 2\pi\nu_p/\nu_r\). The angle traversed during this time is
\[ \Delta \theta = 2\pi(\nu_p/\nu_r) \sqrt{\nu_{x0}^2 + \nu_{y0}^2}. \] (49)

The rate at which stars move into one of the four loss ellipses is given roughly by the number of stars that lie an angular distance \(\Delta \theta\) from one side of a loss ellipse, divided by \(\Delta t\).

This is not quite correct however, since a star may precess past the loss ellipse before it has had time to reach periapse. We carry out a more exact calculation by assuming that the torus is uniformly populated at some initial time, with unit total number of stars. To simplify the calculation, we transform to a new phase plane defined by
\[ \psi = \frac{\nu_{x0}^2 x_0^2 \theta_1 + \nu_{y0}^2 y_0^2 \theta_2}{\sqrt{\nu_{x0}^2 x_0^2 + \nu_{y0}^2 y_0^2}}, \] (50)
\[ \vartheta = \frac{-\nu_{y0} x_0 \ell_{x0} y_0 \theta_1 + \nu_{x0} \ell_{x0} y_0 \theta_2}{\sqrt{\nu_{x0}^2 x_0^2 + \nu_{y0}^2 y_0^2}}. \] (51)

With this transformation, the phase velocity becomes
\[ \psi = (\nu_{x0}^2 x_0^2 + \nu_{y0}^2 y_0^2)^{1/2}, \quad \vartheta = 0 \] (52)
and the loss regions become circles of radius \(\ell\). The angular displacement in one radial period is
\[ \Delta \psi = 2\pi(\nu_r/\nu_r) \left( \nu_{x0}^2 x_0^2 + \nu_{y0}^2 y_0^2 \right)^{1/2}. \] (53)

The density of stars is \((4\pi^2\ell_{x0}\ell_{y0})^{-1}\).

At any point in the \((\psi, \vartheta)\) plane, stars have a range of radial phases. Assuming that the initial distribution satisfies Jeans’ theorem, stars far from the loss regions are uniformly distributed in \(\chi\) where
\[ \chi = P^{-1} \int_{r_p}^r \frac{dr}{v_r}; \] (54)
here \(P \equiv 2\pi/\nu_r\) is the radial period, \(r_p\) is the periapse distance and \(v_r\) is the radial velocity. The integral is performed along the orbit, hence \(\chi\) ranges between 0 and 1 as \(r\) varies from \(r_p\) to apoapse and back to \(r_p\). (\(\chi = w \mod 2\pi\), where \(w\) is mean anomaly).

Figure S shows how stars move in the \((\chi, \psi)\) plane at fixed \(\vartheta\). The loss region extends in \(\psi\) distance \(2\sqrt{\ell^2 - \vartheta^2}\), from \(\psi_{in}\) to \(\psi_{out}\). Stars are lost to the BH if they reach periapse while in this region.

Two regimes must be considered, depending on whether \(\Delta \psi\) is less than or greater than \(\psi_{out} - \psi_{in}\).

1. \(\Delta \psi < \psi_{out} - \psi_{in}\) (Figure S). In one radial period, stars in the orange region are lost. One-half of this region lies within the loss ellipse; these are stars with \(\ell < \ell_0\) but which have not yet attained periapse. The persistence of stars inside the “loss cone” is similar to what occurs in the case of diffusional loss cone repopulation, where there is also a “boundary layer”, the width of which depends on the ratio of the relaxation time to the radial period (e.g. Cohn & Kulsrud (1978)). The other one-half consists of stars that have not yet entered the loss region. The area of the orange region is equal to the area of a rectangle of unit height and width \(\Delta \psi\) since stars are distributed uniformly on the \((\chi, \psi)\) plane, the number of stars lost per radial period is equal to the total number of stars, of any radial phase, contained within \(\Delta \psi\).

2. \(\Delta \psi > \psi_{out} - \psi_{in}\) (Figure S). In this case, some stars manage to cross the loss region without being captured. The area of the orange region is equal to that of a rectangle of unit height and width \(\psi_{out} - \psi_{in}\). The number of stars lost per radial period is therefore equal to the number of stars, of arbitrary radial phase, contained within \(\psi_{out} - \psi_{in} = 2\sqrt{\ell^2 - \vartheta^2}\).

To compute the total loss rate, we integrate the loss per radial period over \(\vartheta\). It is convenient to express the results in terms of \(q\) where
\[ \frac{\Delta \psi}{2\ell} = \frac{\pi \nu_r \ell_{x0}^{-1}}{\nu_r} \sqrt{\nu_{x0}^2 x_0^2 + \nu_{y0}^2 y_0^2}. \] (55)
where $\Delta \psi > \psi_{\text{in}} - \psi_{\text{out}}$.

$q \ll 1$ corresponds to an “empty loss cone” and $q \gg 1$ to a “full loss cone”. However we note that – for any $q < 1$ – there are values of $\vartheta$ such that the width of the loss region, $\psi_{\text{out}} - \psi_{\text{in}}$, is less than $\Delta \psi$. In terms of the integral $W$ defined above (28), $q$ becomes simply

$$q = \frac{P_{\nu p}}{6 \ell_*} \sqrt{W}. \quad (56)$$

Unlike the case of collisional loss cone refilling, where $q = q(E)$ is only a function of energy, here $q$ is also a function of a second integral $W$. Pyramid orbits with small opening angles will have small $W$ and small $q$.

The area on the $(\psi, \vartheta)$ plane that is lost, in one radial period, into one of the four loss regions is

$$2 \int_0^{\vartheta_c} \Delta \psi d\vartheta + 2 \int_{\vartheta_c}^{\vartheta_r} (\psi_{\text{out}} - \psi_{\text{in}}) d\vartheta \quad (57)$$

where

$$\vartheta_c \equiv \ell_* \sqrt{1 - q^2} \quad (58)$$

is the value of $\vartheta$ where $\Delta \psi = \psi_{\text{out}} - \psi_{\text{in}}$; for $q \geq 1$,

$$\vartheta_c = 0. \quad \text{For} \ q \leq 1, \ \text{the area integral becomes}$$

$$q = \frac{P_{\nu p}}{6 \ell_*} \sqrt{W}. \quad (56)$$

and for $q > 1$ it is $\pi \ell_*^2$. The function $f(q)$ varies from $f(0) = 1$ to $f(1) = \pi/4 \approx 0.785$.

The area on the phase plane that is lost each radial period can be interpreted in a very simple way geometrically, as shown in Figure 9.

Considering that there are four loss regions, the instantaneous total loss rate $F$, in dimensionless units, is

$$F = f(q) \frac{2 \ell_0}{\pi^2 \ell x_0 \ell y_0} \sqrt{\nu_x^2 \nu_y^2 + \nu_x^2 \nu_y^2} = \frac{\mu}{P_{\nu p}} \frac{4 q f(q)}{\pi}$$

for $0 \leq q \leq 1$, (60a)

$$F = q^{-1} \frac{\ell_0}{2 \pi \ell x_0 \ell y_0} \sqrt{\nu_x^2 \nu_y^2 + \nu_x^2 \nu_y^2} = \frac{1}{2 \pi^2} \frac{\ell_0^2}{x_0 y_0} \nu_r$$

for $q > 1$. (60b)

The second expression for the loss rate, equation (60b), can be called the “full-loss-cone” loss rate, since it corresponds to completely filling and emptying the loss regions in each radial step (Figure 3). Note that the loss rate for $q < 1$ is $\sim q$ times the full-loss-cone loss rate. A similar relation holds in the case of collisionally repopulated loss cones (Cohn & Kulsrud 1978).

The inverse of the loss rate $F$ gives an estimate of the time $t_{\text{drain}}$ required to drain an orbit, or equivalently the time for a single star, of unknown initial phase, to go into the BH. In this approximation, the loss rate remains constant until $t = t_{\text{drain}}$ at which time the torus
is completely empty. In reality the draining time will always be longer than this, since after $\sim 1$ precessional periods, some parts of the torus that are entering the loss regions will be empty and the loss rate will drop below equation (61). For $\Delta \psi > \psi_{in} - \psi_{out}$, the downstream density in Figure 8 integrated over radial phase, is easily shown to be $1 - q^{-1} \sqrt{1 - \ell^2/\ell_{min}^2}$ times the upstream density while for $\Delta \psi < \psi_{in} - \psi_{out}$ the downstream density is zero. Integrated over $\theta$, the downstream depletion factor becomes

$$1 - \frac{\pi}{4q} - \sqrt{1 - q^2(1 + q)} + \frac{1}{2q} \sin^{-1} \sqrt{1 - q^2}$$

(61)

for $q \leq 1$ and $1 - \pi/4q$ for $q > 1$; it is 0 for $q = 0$, $\sim 0.215$ for $q = 1$ and 1 for $q \to \infty$. For small $q$, the torus will become striated, containing strips of nearly-zero density interleaved with undepleted regions; the loss rate will exhibit discontinuous jumps whenever a depleted region encounters a new loss ellipse and the time to totally empty the torus will depend in a complicated way on the frequency ratio $\nu_x/\nu_y$ and on $\ell$. For large $q$, the loss rate will drop more smoothly with time, roughly as an exponential law with time constant $\sim t_{\text{drain}}$.

We postpone a more complete discussion of loss cones in the triaxial geometry to a future paper. Here we make a few remarks about pyramids with arbitrary opening angles, i.e. for which $e_{x0}, e_{y0}$ are not required to be small.

For each orbit one can compute $\mu$, the fraction of the torus occupied by the loss cone (equation 45), by numerically integrating the equations of motion (13) and analyzing the probability distribution for instantaneous values of $\ell^2$: $P(\ell^2 < X) \propto X - \ell_{min}^2$, where $\ell_{min}^2$ allows for a nonzero lower bound on $\ell^2$. Almost all pyramids have $\ell_{min} = 0$, but some of them happen to be resonances (commensurable $\nu_x$ and $\nu_y$) and hence avoid approaching $\ell = 0$. This linear character of the distribution of $\ell^2$ near its minimum corresponds to a linear probability distribution of periapsis radii ($P(\rho_{\text{peri}} < \tau) \propto \tau$), which is natural to expect if we combine a quadratic distribution of impact parameters at infinity with gravitational focusing (see equation 7 of Merritt & Poon (2004)).

The coefficient $\mu$ for each orbit is calculated as $P(\ell^2 < \ell^2)$. As seen from equation (15), the smaller the extent of a pyramid in any direction, the greater $\mu$ – this is true even for orbits with large $e_{x0}$ or $e_{y0}$. While $\mu$ varies greatly from orbit to orbit, its overall distribution over the entire ensemble of pyramid orbits follows a power law:

$$P_\mu(\mu > Y) \approx \frac{Y}{\mu_{min}}^{-2}, \quad \mu_{min} = \frac{\ell_{min}^2}{2\eta^2}$$

(62)

$P_\mu$ is the probability of having $\mu$ greater than a certain value and $\eta$ is the fraction of pyramids among all orbits. The average $\mu$ for all pyramid orbits is therefore $\mu = 2\mu_{min}$, and the average fraction of time that a random orbit of any type and any $\ell$ spends inside the loss cone is $\eta \approx \ell_{min}^2$ (almost independent of the potential parameters $e_x$ and $e_y$) – the same number that would result from an isotropic distribution of orbits in a spherically-symmetric potential.

6. COMPARISON WITH REAL-SPACE INTEGRATIONS

We tested the applicability of the orbit-averaged approach by comparing the orbit-averaged equations of motion, equation (15), with real-space integrations of orbits having the same initial conditions (and arbitrary radial phases). The agreement was found to be fairly good for orbits with semimajor axes $a \lesssim 0.1r_{\text{inf}}$; about 90% of the orbits were found to belong to the same orbital class, and the correspondence between values of $\mu$ and $\ell_{min}^2$ was also quite good for individual orbits. Averaged over the ensemble, the proportion of phase space occupied by the different orbital families, as well as the net flux of pyramids into the BH, is almost the same for the two methods. However, at larger radii, the relative fraction of pyramids and saucers decreases (Figure 8(right)). Since the maximum possible angular momentum for orbits with a given semimajor axis $a$ grows faster than $\sqrt{GMa}$, this means that the fraction of pyramid orbits among all $a$ (not just low-$\ell$) orbits is even smaller. For orbits with semimajor axis $a \gtrsim r_{\text{inf}}$, the frequency of radial oscillation becomes comparable to the frequencies of precession, and when these overlap, orbits tend to become chaotic. (Weakly chaotic behavior starts earlier). So low-$\ell$ orbits with $a > 1.5r_{\text{inf}}$ are mostly chaotic, as seen from Figure 10 confirming that regular pyramid orbits (along with saucers) exist only within BH sphere of influence (Poon & Merritt (2001)).

7. EFFECTS OF GENERAL RELATIVITY

In the previous sections we considered the BH as a Newtonian point mass. In general relativity (GR), the gravitational field of the BH is more complicated, and this will affect the behavior of orbits with distances of closest approach that are comparable to $r_g \equiv GM_a/c^2$.

For a non-spinning BH, the lowest order post-Newtonian effect is advance of the periapsis, which acts in the opposite sense to the precession due to an extended
Orbital structure of triaxial nuclei

mass distribution. The GR periapse advance is

$$\Delta \omega = \frac{6\pi GM_*}{c^2 (1 - c^2)a} \quad (63)$$

per radial period, with c the speed of light (Weinberg 1972), making the orbit-averaged precession frequency

$$\nu_{GR} = \frac{3GM_*}{c^2 a l^2}.$$  \quad (64)

We can approximate the effects of this precession by adding an extra term to the orbit-averaged Hamiltonian (13):

$$H = -\frac{3}{2} \ell^2 + \epsilon_b H_b + \epsilon_c H_c - \nu \ell \quad (65a)$$

$$\nu \equiv \nu_{GR} \frac{\ell^2}{\nu_p} = \frac{3GM_0}{c^2 a} \frac{\nu_p}{r_{Schw}} \frac{M_0}{M(a)} \quad (65b).$$

This is equivalent to adding the term $$\nu \ell^2$$ to the equation of motion for $$\omega$$, i.e., to the right-hand side of $$d\omega/d\tau = \partial H/\partial \ell$$. When $$\ell = \ell_{\text{crit}}$$, where

$$\ell_{\text{crit}} = \left(\frac{\nu}{3}\right)^{1/3},$$  \quad (66)

the precession due to GR exactly cancels the precession due to the spherical component of the distributed mass. Since the angular momentum of a pyramid orbit approaches arbitrarily close to zero in the absence of GR, there will always come a time when its precession is dominated by the effects of GR, no matter how small the value of the dimensionless coefficient $$\nu$$.

We again restrict consideration to the simplified Hamiltonian (13), valid for $$\epsilon_b, c \ll 1$$, $$\ell^2 \lesssim \epsilon_c$$, now with the added term due to GR. This Hamiltonian may be rewritten as

$$\frac{5}{2} \epsilon_c - H = \left[\frac{3}{2} \ell^2 + \frac{\epsilon_x}{\ell}\right] + \frac{5}{2} \epsilon_c \epsilon_y^2 + \frac{5}{2} (\epsilon_c - \epsilon_b) \epsilon_y^2$$

$$\equiv P(\ell) + Q(\epsilon_x, \epsilon_y),$$  \quad (67)

where $$P$$ and $$Q$$ denote the expressions in the first and second sets of square brackets. The minimum of $$P(\ell)$$ occurs at $$\ell = \ell_{\text{crit}}$$:

$$P_{\text{min}} = \frac{5}{12} \epsilon_c.$$

The function $$Q$$ can vary from 0 to some maximum value $$Q_{\text{max}}$$ due to the limitation that $$\epsilon_x + \epsilon_y \leq 1$$.

Two differences from the Newtonian case are apparent.

1) For each value of $$(\epsilon_x, \epsilon_y)$$ (and therefore $$Q$$), there are now two allowed values of $$\ell$$. One of these is smaller than $$\ell_{\text{crit}}$$ while the other is greater (Figure 11).

2) Both the minimum and maximum values of $$\ell$$ – both of which correspond to the maximum value of $$P$$ (Figure 11) – are attained when $$Q = 0$$, i.e. when $$\epsilon_x = \epsilon_y = 0$$. The maximum of $$Q$$ corresponds to $$\ell = \ell_{\text{crit}}$$. In the Newtonian case, the minimum of $$\ell$$ corresponds to the maximum of $$Q$$.

7.1. Planar orbits

We first consider orbits confined to the $$y - z$$ plane ($$\epsilon_x = 0$$, hence $$\Omega = \pi/2$$, $$\omega = 0$$ throughout the evolution). Namely, we start an orbit from $$\omega = \pi/2$$ ($$\epsilon_y = 0$$)

$$Q_{\min} = \nu_{GR}^2/6.$$  \quad (69)

If $$\ell > \ell_{\text{crit}}$$, the orbit behaves like a Newtonian LAT (Figure 12 case a); it has $$\omega = 0$$ and $$\ell > \ell_{\text{crit}}$$. On the other hand, $$\ell < \ell_{\text{crit}}$$, the orbit is again a LAT, but now it precesses in the opposite direction ($$\omega > 0$$) due to the dominance of GR, and $$\ell$$ never climbs above $$\ell_{\text{crit}}$$ (Figure 12 case e).

In these cases the condition $$\omega = 0$$ gives the extremum of $$\ell$$, which is found from equation (69):

$$\frac{3}{2} \ell_{0+}^2 + \frac{\epsilon}{\ell_{0+}} = \frac{3}{2} \ell_{\text{crit}}^2 + \frac{\epsilon}{\ell_{\text{crit}}} + \frac{\nu_{GR}^2}{6};$$  \quad (71)

$$\ell_{0+}$$ and $$\ell_{0-}$$ are the upper and lower positive roots of this equation.

If $$\ell_0 > \ell_{0+}$$, the orbit behaves like a Newtonian LAT (Figure 12 case a); it has $$\omega < 0$$ and $$\ell > \ell_{\text{crit}}$$.

$$\ell_0 < \ell_{0-}$$, the orbit is again a LAT, but now it precesses in the opposite direction ($$\omega > 0$$) due to the dominance of GR, and $$\ell$$ never climbs above $$\ell_{\text{crit}}$$ (Figure 12 case e).

In these cases the condition $$\omega = 0$$ gives the extremum of $$\ell$$, which is found from equation (69):

$$\frac{3}{2} \ell_{\text{extr,L}}^2 + \frac{\epsilon}{\ell_{\text{extr,L}}} = \frac{3}{2} \ell_{0+}^2 + \frac{\epsilon}{\ell_{0+}} - \frac{\nu_{GR}^2}{6}.$$  \quad (72)

This extremum appears to be a minimum ($$\ell_{\text{extr,L}} < \ell_{0-}$$) if $$\ell_0 > \ell_{0+}$$ and a maximum ($$\ell_{\text{extr,L}} > \ell_{0-}$$) if $$\ell_0 < \ell_{0-}$$. 

![Fig. 11.--- Illustrating the allowed variations in angular momentum $$\ell$$ for orbits in the presence of general relativistic precession. The solid (red) curve represents the function $$P(\ell)$$ (equation 67); the dashed (blue) parabola is the same function in the Newtonian case ($$x = 0$$). If $$x \neq 0$$, the GR function has a maximum at $$\ell_{\text{crit}}$$ (equation 66). Orbits make excursions along the curve $$P(\ell)$$ in the range from a certain value $$P_{\text{max}}$$ to $$P_{\text{max}} - Q_{\text{max}}$$ (here $$Q_{\text{max}}$$ is given for the case of planar orbits of §7.1 and equals $$\frac{3}{2} (\epsilon_4 - \epsilon_5) = \nu_{GR}^2/6$$. If during such an excursion $$\ell$$ does not cross $$\ell_{\text{crit}}$$, then the orbit resides on one branch of $$P(\ell)$$, typically remaining regular. Otherwise it flips to the other branch, reaching lower values of $$\ell$$, becoming a (typically chaotic) LAT or pyramid orbit.](image-url)
Pyramid orbits are those that reach \( \ell = \ell_{\text{crit}} \). \( \dot{\varpi} \) changes sign exactly at \( \ell_{\text{crit}} \), but the angular momentum continues to decrease beyond the point of turnaround, reaching its minimum value only when \( \varpi \) returns again to \( \pi/2 \), i.e. the \( z \)-axis. The two semiperiods of oscillation are not equal: the first (\( \ell > \ell_{\text{crit}} \) and \( \dot{\varpi} < 0 \)) is slower, the other is more abrupt (Figure 12 cases b, d). In effect, the orbit is “reflected” by striking the GR angular momentum barrier. After the orbit precesses past the \( z \) axis in the opposite sense, the angular momentum begins to increase again, reaching its original value after the precession in \( \varpi \) has gone a full cycle and the orbit has returned to the \( z \) axis from the other side.

If \( \ell_0 = \ell_{\text{crit}} \), there is no oscillation at all – the GR and extended mass precession balance each other exactly (Figure 12 case c). For \( \ell_0 < \ell_{\text{crit}} \) the orbit precesses in the opposite sense to the Newtonian precession.

We can find the extreme values of \( \ell \) by setting \( \dot{\ell} = 0 \) in equation (70). This occurs for \( \varpi = \pi/2 \), i.e. for \( Q = 0 \) or \( P(\ell) = P(\ell_0) \). This gives

\[
\ell_{\text{extr},0} = \frac{\ell_0}{2} \left( 1 + 8 \frac{\ell_{\text{crit}}^2}{\ell_0^2} - 1 \right). 
\]  

(73)

If \( \ell_0 > \ell_{\text{crit}} \), this root corresponds to the minimum \( \ell \), with \( \ell_0 \) the maximum value; in the opposite case they exchange places. For \( \kappa \ll 3 \ell_0^3 \) this additional root is

\[
\ell_{\text{min}} \approx \frac{2 \ell_{\text{crit}}^3}{3 \ell_0^2}. 
\]  

(74)

Thus the minimum angular momentum attained by a pyramid orbit in the presence of GR is approximately proportional to \( \kappa \). Note the counter-intuitive result that the pyramid orbit with the widest base (largest \( \ell_0 \)) comes closest to the BH.

Figure 13 shows the dependence of the maximum and minimum values of \( \ell \) on \( \ell_0 \) for the various orbit families.

### 7.2. Three-dimensional pyramids

In the case of pyramid orbits that are not restricted to a principal plane, numerical solution of the equations of motion derived from the Hamiltonian (65a) are observed to be generally chaotic, increasingly so as \( \kappa \) is increased (Figure 14). This may be attributed to the “scattering” effect of the GR term \( \kappa/\ell \) in the Hamiltonian, which causes the vector \((e_x, e_y)\) to be deflected by an almost random angle whenever \( \ell \) approaches zero. In the limit that the motion is fully chaotic, \( H \) remains the only integral of the motion. The following argument suggests that the minimum value of the angular momentum attained in this case should be the same as in equation (73).

Suppose that the Hamiltonian (67) is the only integral that remains. Then the vector \((e_x, e_y)\) can lie anywhere inside an ellipse

\[
Q(e_x, e_y) = \frac{5}{2} \left[ \epsilon_c e_x^2 + (\epsilon_c - \epsilon_b) e_y^2 \right] \leq Q_{\text{max}}, 
\]  

(75)

whose boundary is given by

\[
Q_{\text{max}} = \frac{5}{2} \epsilon_c - H - P_{\min}. 
\]  

(76)

\[ T. \text{ Alexander has suggested that these be called “windshield-wiper orbits.”} \]

This ellipse defines the base of the “pyramid” (which now rather resembles a cone). As in the planar case, the maximum and minimum values of \( \ell \) are attained not on the boundary of this ellipse (i.e. the corners in the Newtonian case), but at \( e_x = e_y = 0 \), where \( Q = 0 \) and \( P \) attains its maximum. These values are given by the roots of the equation \( P(\ell) = \frac{2}{3} \epsilon_c - H \), or

\[
3 \ell^3 - (5 \epsilon_c - 2H) \ell + 6 \epsilon_c^2 = 0. 
\]  

(77)

The two positive roots of this cubic equation are given by

\[
\ell_{\text{min, max}} = \frac{2}{3} \sqrt[3]{5 \epsilon_c - 2H} \sin \left( \frac{\pi}{6} \pm \phi \right), 
\]  

(78)

\[
\phi = \frac{1}{3} \arccos \left( \frac{9 \kappa}{(5 \epsilon_c - 2H)^{3/2}} \right). 
\]

The plus sign in the argument of the sine function gives \( \ell_{\text{max}} \) while the minus sign gives \( \ell_{\text{min}} \). These two values are linked by a simple relation:

\[
\ell_{\text{min}} = \frac{\ell_{\text{max}}}{2} \left( \sqrt{1 + 8 \kappa \ell_{\text{max}}^3/3} - 1 \right) \approx \frac{2}{3} \frac{\kappa}{\ell_{\text{max}}^2}, 
\]  

(79)
Orbital structure of triaxial nuclei

Fig. 13.— Minimum and maximum values of \( \ell \) for a series of orbits with initial conditions \( \ell = \ell_0, \omega = \pi/2, \ell_x = 0, \Omega = \pi/2 \). Potential parameters are \( \epsilon_c = 10^{-2}, \epsilon_b = \epsilon_c/2, \kappa = 10^{-4} \). The straight line is \( \ell = \ell_0 \); dashed line is the extremum for pyramids, equation (73). These two curves intersect at \( \ell_{\text{crit}} \) (equation 59), where they exchange roles. For \( \ell > \ell_{\text{crit}} \), \( \ell < \ell_{\text{crit}} \) (equation 61) the orbit is a tube, and the minimum (or maximum) is given by equation (72). Dotted grey line shows the leading frequency of \( \omega \) oscillations, \( \nu_{\omega} \approx 10^{-2} \); for high-\( \ell \) orbits \( \nu_{\omega} \approx 3\ell \), for orbits dominated by GR precession \( \nu_{\omega} \approx 2\pi/\ell^2 \). Letters denote the position of orbits shown in Figure 12.

where the latter approximate equality holds for \( \kappa \ll \ell^3_{\text{max}} \). In the same approximation

\[
\ell_{\text{min}} \approx \frac{2\kappa}{5\epsilon_c - 2H}, \quad \ell^2_{\text{max}} \approx \frac{5\epsilon_c - 2H}{3}.
\]  

Equation (72) for planar pyramids is a special case of this relation where \( \ell_0 = \ell_{\text{max}} \).

The ellipse (75) serves as a “reflection boundary” for trajectories that come below \( \ell \approx \ell_{\text{crit}} \). If this happens, the vector \((\epsilon_x, \epsilon_y)\) is observed to be quickly “scattered” by an almost random angle (Figure 14, right, denoted by \( \epsilon_3 \)).

Roughly speaking, all pyramid orbits and some tube orbits (those that may attain \( \ell \leq \ell_{\text{crit}} \)) will be chaotic.

The distinction between pyramids and chaotic tubes is in the radius of this ellipse: pyramids by definition have a fixed sign of \( \epsilon_z \), or \( \epsilon^2_x + \epsilon^2_y < 1 \), which means that the ellipse (75) should not touch the circle \( \epsilon^2_x + \epsilon^2_y = 1 \). Hence pyramids have \( Q \leq \frac{3}{2}(\epsilon_c - \epsilon_b) \), and

\[
\frac{5}{2}\epsilon_b - P_{\text{min}} \leq H \leq \frac{5}{2}\epsilon_c - P_{\text{min}}.
\]  

This condition is different from the one described in [44] even in the case \( \kappa = 0 = P_{\text{min}} \), since now pyramids do not coexist with LAT orbits.

The condition for LATs to be chaotic (i.e. to pass through \( \ell_{\text{crit}} \)) is \( P_{\text{min}} + Q_{\text{max}} \leq \frac{5}{2}\epsilon_c - H \). For LATs the ellipse (73) always intersects the unit circle, so this condition can be satisfied for \( -P_{\text{min}} \leq H \leq \frac{5}{2}\epsilon_b - P_{\text{min}} \). However, this is a necessary but not sufficient condition

6 A small fraction of the “flipping” orbits, especially those that oscillate near \( \ell_{\text{crit}} \) (close to the lowest point on the \( P(\ell) \) curve of Figure 11), may retain regularity by virtue of being resonant.

for a chaotic LAT: some orbits from this range do not attain \( \ell < \ell_{\text{crit}} \) because of the existence of another integral of motion besides \( H \) (that is, they are regular).

Finally, we consider the character of the motion when the precession is dominated by GR, as would be the case very near the BH. This is equivalent to staying on the left branch of \( P(\ell) \), with \( \ell_{\text{min},\text{max}} \ll \ell_0 \). In this limit there is a second short time scale in addition to the radial period, the time for GR precession. This situation is similar to the high-\( \ell \) case (§4.3), in the sense that we can carry out a second averaging over \( \omega \) and obtain the equations that describe the precession of an annulus due to the triaxial torques. The orbits in this case are again short- or long-axis tubes. The only difference from §4.3 is that we have to add the term \(-\kappa/\ell \) to the averaged Hamiltonian (11), but since \( \ell \) is constant in this approximation, the equations of motion for \( \ell, \Omega \) do not change.

These very-low-\( \ell \) regular tube orbits can be easily captured by the BH, however their number is very small and we do not consider them when computing the total capture rate.

We argue in §8 that the conservation of \( \ell \) for orbits in this limit can have important consequences for resonant relaxation.

7.3. Capture of orbits by the BH in the case of GR

The inclusion of general relativistic precession has the effect of limiting the maximum eccentricity achievable by a pyramid orbit. However, if \( \ell_{\text{min}} \leq \ell_\ast \), an orbit can still come close enough to the BH to be disrupted or captured. Introducing the quantity \( w \equiv \ell_{\text{min}}/\ell_\ast \), we can write

\[
w \equiv \frac{\ell_{\text{min}}}{\ell_\ast} \approx \frac{1}{\ell_\ast} \frac{2\kappa}{5\epsilon_c - 2H} \geq \frac{3}{5\epsilon_c} \frac{\nu_r \ell_\ast}{\nu_\perp},
\]  

where we used (61) and set \( H = 0 \) as a lower limit for pyramid orbits (orbits with the smallest \( H \) have the largest \( \ell_{\text{max}} \) and the smallest \( \ell_{\text{min}} \)). Comparison with equation (59), with \( W \leq (15\epsilon_c)^2 \), shows that

\[
w \approx \frac{3\pi}{\Theta} q^{-1}.
\]  

Roughly speaking, the condition that stars be captured \( w < 1 \) is equivalent to the statement that the loss cone is full \( q > 1 \). This is not a simple coincidence: a full loss cone implies that for low-\( \ell \) orbits the mean change of \( \ell \) during one radial period \( \sim \nu_r \ell_0 \nu_\perp/\nu_r \) is of order \( \ell_\ast \), while the condition \( w = 1 \) requires that for the lowest allowable \( \ell \), the GR precession rate (61) is comparable to the radial frequency. These two conditions are roughly equivalent.

We can express this necessary condition for capture in terms of more physically relevant quantities. Writing equation (14a) as

\[
\frac{\nu_c}{\nu_r} \approx \frac{1}{2} \frac{M(a)}{M_\ast},
\]  

and approximating \( r_{\text{inf}} \) of equation (2) as

\[
r_{\text{inf}} \approx \frac{GM_\ast}{\sigma^2} \equiv r_0
\]  

with \( \sigma \) the one-dimensional stellar velocity dispersion at
The Milky Way BH constitutes one extreme of the BH mass distribution. Writing $\Theta \approx 10$ (solar-mass main sequence stars), $\sigma \approx 10^2$ km s$^{-1}$, and $\gamma = 3/2$ gives

$$\epsilon_c^{1/2} \frac{a}{r_0} \gtrsim 10^{-2}$$

A dimensionless triaxiality of order unity is reasonable for a giant elliptical galaxy.

In § 8 we estimate the loss rate using the expression for the full loss cone rate, with the modification that the fraction of time $\mu$ an orbit spends inside the loss cone is now given not by (48), but by

$$\mu \approx \frac{\ell^2 - \ell_{\text{min}}^2}{\ell_{\text{max}}^2 - \ell_{\text{min}}^2}. \quad (89)$$

This relation implies that the instantaneous value of $\ell^2$ is distributed uniformly in the range $[\ell_{\text{min}}^2, \ell_{\text{max}}^2]$. This is a good approximation for chaotic pyramid orbits and a reasonable (within a factor of few) approximation for chaotic LATs (and also for regular orbits).

In the next section we point out the importance of the angular momentum limit for the rate of gravitational wave events due to inspiral of compact stellar remnants.

8. CONNECTION WITH “RESONANT RELAXATION”

Resonant relaxation (RR) is a phenomenon that arises in stellar systems exhibiting certain regularities in the motion (Rauch & Tremaine 1996; Hopman & Alexander 2006a). Due to the discreteness of the stellar distribution, torques acting on a test star from all other stars do not cancel exactly, and there is a residual torque that produces a change in the angular momentum:

$$\frac{dL}{dt} \approx \sqrt{N} \frac{Gm}{a} = L_c \frac{\sqrt{N} \frac{M}{\ell}}{2\pi P^{-1}}$$

(90)

(here $m$ is the stellar mass, $P = 2\pi/\mu_r$ is the radial period, $L_c = \sqrt{G\frac{M}{a}}$ is the angular momentum of a circular orbit with radius $a$, and $N$ is roughly the number of stars within a sphere of radius $a$). In a non-resonant system this net torque changes the direction randomly after each radial period, but in the case of near-Keplerian motion, for example, orbits remain almost the same for many radial periods, so the change of angular momentum produced by this torque continues in the same direction for a much longer time, the so-called coherence time $t_{\text{coh}}$, until the orientation of either the test star’s orbit or the other stars’ orbits change significantly. If this decoherence is due to precession of stars in their mean field, then

$$t_{\text{coh}} \approx t_M \equiv \nu_{\text{p}}^{-1} \approx \frac{M_\star}{m} \frac{P}{N} \quad (91)$$

where the relevant precession time is that for an orbit of average eccentricity.

The total change of $L$ during $t_{\text{coh}}$ is

$$\langle \Delta L \rangle_{\text{coh}} \approx \sqrt{N} \frac{Gm}{a} t_{\text{coh}} \approx \frac{L_c}{\sqrt{N}}. \quad (92)$$

On timescales longer than $t_{\text{coh}}$ the angular momentum experiences a random walk with step size $\langle \Delta L \rangle_{\text{coh}}$ and time step $t_{\text{coh}}$. The relaxation time is defined as the time required for an orbit to change its angular momentum by $L_c$, and hence it is given by

$$t_{\text{RR,s}} \approx \left( \frac{L_c}{\Delta L} \right)^2 t_{\text{coh}} \approx \frac{M_\star}{m}. \quad (93)$$

The above argument describes “scalar” resonant relaxation, in which both the magnitude and direction of $L$ can change. On longer timescales, precessing orbits fill annuli, which also exert mutual torques; however, since these torques are perpendicular to $L$, they may change only the direction, not the magnitude of $L$. This effect is dubbed vector resonant relaxation (VRR), and its coherence time is given by the time required for orbital planes

\[ r = r_{\text{infl}}, \text{the condition } w \leq 1 \text{ becomes} \]

\[ \frac{1}{\epsilon_c \sqrt{\Theta}} \frac{a}{c} \left( \frac{a}{r_0} \right) \gamma^{-7/2} \lesssim 1. \tag{86} \]

The Milky Way BH constitutes one extreme of the BH mass distribution. Writing $\Theta \approx 10$ (solar-mass main sequence stars), $\sigma \approx 10^2$ km s$^{-1}$, and $\gamma = 3/2$ gives

\[ \epsilon_c^{1/2} \frac{a}{r_0} \gtrsim 10^{-2} \tag{87} \]

e.g. for $a = 0.1r_0 \approx 0.3$ pc, $\epsilon_c \gtrsim 10^{-3}$ is required for stars to be captured. This is a reasonable degree of triaxiality for the Galactic center.

At the other mass extreme, we consider the galaxy M87, for which $\sigma \approx 350$ km s$^{-1}$ and $\Theta \approx 3$. Setting $\gamma = 0.5$, corresponding to a low-density core, we find

\[ \epsilon_c^{1/3} \frac{a}{r_0} \gtrsim 10^{-1}. \tag{88} \]

A dimensionless triaxiality of order unity is reasonable for a giant elliptical galaxy.

In § 8 we estimate the loss rate using the expression for the full loss cone rate, with the modification that the fraction of time $\mu$ an orbit spends inside the loss cone is now given not by (48), but by

\[ \mu \approx \frac{\ell^2 - \ell_{\text{min}}^2}{\ell_{\text{max}}^2 - \ell_{\text{min}}^2}. \tag{89} \]

This relation implies that the instantaneous value of $\ell^2$ is distributed uniformly in the range $[\ell_{\text{min}}^2, \ell_{\text{max}}^2]$. This is a good approximation for chaotic pyramid orbits and a reasonable (within a factor of few) approximation for chaotic LATs (and also for regular orbits).

In the next section we point out the importance of the angular momentum limit for the rate of gravitational wave events due to inspiral of compact stellar remnants.

8. CONNECTION WITH “RESONANT RELAXATION”

Resonant relaxation (RR) is a phenomenon that arises in stellar systems exhibiting certain regularities in the motion (Rauch & Tremaine 1996; Hopman & Alexander 2006a). Due to the discreteness of the stellar distribution, torques acting on a test star from all other stars do not cancel exactly, and there is a residual torque that produces a change in the angular momentum:

\[ \frac{dL}{dt} \approx \sqrt{N} \frac{Gm}{a} = L_c \frac{\sqrt{N} \frac{M}{\ell}}{2\pi P^{-1}} \tag{90} \]

(here $m$ is the stellar mass, $P = 2\pi/\mu_r$ is the radial period, $L_c = \sqrt{G\frac{M}{a}}$ is the angular momentum of a circular orbit with radius $a$, and $N$ is roughly the number of stars within a sphere of radius $a$). In a non-resonant system this net torque changes the direction randomly after each radial period, but in the case of near-Keplerian motion, for example, orbits remain almost the same for many radial periods, so the change of angular momentum produced by this torque continues in the same direction for a much longer time, the so-called coherence time $t_{\text{coh}}$, until the orientation of either the test star’s orbit or the other stars’ orbits change significantly. If this decoherence is due to precession of stars in their mean field, then

\[ t_{\text{coh}} \approx t_M \equiv \nu_{\text{p}}^{-1} \approx \frac{M_\star}{m} \frac{P}{N} \quad (91) \]

where the relevant precession time is that for an orbit of average eccentricity.

The total change of $L$ during $t_{\text{coh}}$ is

\[ \langle \Delta L \rangle_{\text{coh}} \approx \sqrt{N} \frac{Gm}{a} t_{\text{coh}} \approx \frac{L_c}{\sqrt{N}}. \quad (92) \]

On timescales longer than $t_{\text{coh}}$ the angular momentum experiences a random walk with step size $\langle \Delta L \rangle_{\text{coh}}$ and time step $t_{\text{coh}}$. The relaxation time is defined as the time required for an orbit to change its angular momentum by $L_c$, and hence it is given by

\[ t_{\text{RR,s}} \approx \left( \frac{L_c}{\Delta L} \right)^2 t_{\text{coh}} \approx \frac{M_\star}{m}. \quad (93) \]

The above argument describes “scalar” resonant relaxation, in which both the magnitude and direction of $L$ can change. On longer timescales, precessing orbits fill annuli, which also exert mutual torques; however, since these torques are perpendicular to $L$, they may change only the direction, not the magnitude of $L$. This effect is dubbed vector resonant relaxation (VRR), and its coherence time is given by the time required for orbital planes

Fig. 14.— Three pyramid orbits with the same initial conditions ($\ell = 0.05, \ell_z = 0.02, \omega = \Omega = \pi/2; \epsilon_c = 0.01, \epsilon_b = 0.005$) and three values of the GR coefficient $\kappa$ (equation 55). Left: $\kappa = 0$ (regular); middle: $\kappa = 10^{-6}$ (weakly chaotic); right: $\kappa = 10^{-5}$ (strongly chaotic). The green ellipse marks the maximal extent of the $(e_x, e_y)$ vector, equation 59, i.e. $\ell = \ell_{\text{crit}}$, equation 60; red segments correspond to $\ell < \ell_{\text{crit}}$, blue to $\ell > \ell_{\text{crit}}$ and to the nonrelativistic case.
to change. In a spherically symmetric system the only mechanism that changes orbital planes is the relaxation itself. Hence for VRR the coherence time is given by setting $|dL/dt| = L_c/t_{\text{coh}}$ in equation (90):

$$t_{\text{coh}} \equiv t_{\Omega,\text{VRR}} \approx \frac{M_* P}{m \sqrt{N}} \approx \sqrt{N} t_M$$

(94)

and the relaxation time, equation (93), becomes

$$t_{\text{RR,v}} \approx t_{\Omega,\text{VRR}} \approx \frac{P M_*}{m \sqrt{N}}$$

(95)

which is $\sim \sqrt{N}$ times shorter than the scalar relaxation time.

We begin by comparing RR timescales with timescales for orbital change due to a triaxial background potential. Consider a star on a (regular) pyramid orbit confined to the $x-z$ plane. It experiences periodic changes of angular momentum $\ell = L/L_c$ with frequency $\nu \propto \nu_{x0} \nu_p$ and amplitude $\delta \Omega \lessgtr \nu_{x0} / 3$ (24). Hence, the typical rate of change of angular momentum is

$$\frac{dL}{dt} \approx L_c \nu_{x0} (3/2) \approx L_c 5 \epsilon M_m / M_a 2 \pi P^{-1}.$$  \hspace{1cm} (96)

Comparison with (93) shows that the rate of change of angular momentum due to unbalanced torques from the other stars (RR) is greater than the rate of regular precession if $\epsilon \sqrt{N} \gtrsim 1$. However, the coherence time for RR is a typical precession time of stars in the cluster, $\nu_p^{-1}$, whereas pyramids change angular momentum on a longer timescale $(\nu_p \sqrt{5\epsilon})^{-1}$. On the other hand, in the case of RR the angular momentum continues to change in a random-walk manner on timescale longer than $t_{\text{coh}}$, while in the case of precession in triaxial potential its variation is bounded.

Next we consider VRR, which corresponds to changes in orbital planes defined by the angles $\Omega$ and $i = \arccos(\ell / \ell_c)$. The frequency of orbital plane precession in a triaxial potential, $\nu_{\Omega}$, is $\sim \nu_p \sqrt{\epsilon}$ for low-$\ell$ orbits (pyramids and saucers) and even lower for other orbits (Figure 2). The corresponding timescale may be written as

$$t_{\Omega,\text{triax}} \gtrsim \frac{M_* P}{m \sqrt{N} \epsilon}.$$  \hspace{1cm} (97)

Comparison with the VRR timescale (95) shows that $t_{\text{RR,v}} / t_{\Omega,\text{triax}} \lesssim \sqrt{N} \epsilon$. For the Milky Way, these two timescales are roughly equal at $a \approx 0.5$ pc (Figure 15). For sufficiently large $N$ the regular precession due to triaxial torques goes on faster than the relaxation, so the coherence time for VRR is now defined by orbit precession, and the relaxation time itself becomes even longer. On the other hand, for small enough $N$ the VRR destroys orientation of orbital planes before they are substantially affected by triaxial torques. It seems that VRR in triaxial (or even axisymmetric) systems can be suppressed by regular orbit precession; we defer the detailed analysis of relaxation for a future study.

So far we have considered the torques arising under RR as being independent of the torques due to the elongated star cluster. Suppose instead that we identify the $\sqrt{N}$ torques that drive RR with the torques due to the triaxial distortion. The justification is as follows: During the coherent RR phase, the gravitational potential from $N$ orbit-averaged stars can be represented in terms of a multipole expansion. If the lowest-order nonspherical terms in that expansion happen to coincide with the potential generated by a uniform-density triaxial cluster, the behavior of orbits in the coherent RR regime would be identical to what was derived above for orbits in a triaxial nucleus. We stress that this is a contrived model; in general, an expansion of the orbit-averaged potential of $N$ stars will contain nonzero dipole, octupole etc. terms that depend in some complicated way on radius. Nevertheless the comparison seems worth making since (as we argue below) there is one important feature of the motion that should depend only weakly on the details of the potential decomposition.

Equating the torques due to RR

$$T_{\text{RR}} \approx \frac{\sqrt{N} Gm}{r}$$

(98)

with those due to a triaxial cluster,

$$T_{\text{triax}} \approx \frac{Gnm}{r}$$

(99)

our ansatz becomes

$$\epsilon \approx \frac{N^{-1/2}}{a}.$$  \hspace{1cm} (100)

As shown above (77), GR sets a lower limit to the angular momentum of a pyramid orbit (equation 74):

$$\ell_{\min} \approx \frac{\kappa}{\ell_0} \approx \frac{\kappa}{\epsilon} \approx \frac{r_{\text{Schw}}}{a} \frac{M_*}{M(a)} \sqrt{N};$$

(101)

the third term comes from setting $\ell_0 \approx \ell_{\max} \approx \sqrt{\epsilon}$, the maximum value for a pyramid orbit, while the fourth term uses our ansatz (100) and the definition (65) of $\kappa$. Expressed in terms of eccentricity,

$$1 - e_{\max} \approx \left(\frac{r_{\text{Schw}}}{a}\right)^2 \left(\frac{M_*}{m}\right)^2 \frac{1}{N(a)}.$$  \hspace{1cm} (102)

There is another way to motivate this result that does not depend on a detailed knowledge of the behavior of pyramid orbits. If we require that the GR precession time:

$$\nu_{\text{GR}} \approx \frac{\ell^2}{\kappa} \nu_p^{-1}$$

(103)

(eq. 64) be shorter than the time

$$\ell \left|\frac{d\ell}{dt}\right|^{-1} \approx \frac{\ell}{\epsilon} \nu_p^{-1}$$

(104)

for torques to change $\ell$ by of order itself, then

$$\ell \lesssim \frac{\kappa}{\epsilon} \approx \sqrt{N} \kappa \approx \frac{r_{\text{Schw}}}{a} \frac{M_*}{M(a)} \sqrt{N}$$

(105)

as above. In other words, when $\ell \lesssim \ell_{\min}$, GR precession is so rapid that the $\sqrt{N}$ torques are unable to change the angular momentum significantly over one precessional period.

In order for this limiting angular momentum to be relevant to RR, the timescale for changes in the background...
potential should be long compared with the time over which an orbit with \( \ell \approx \ell_{\text{min}} \) appreciably changes its angular momentum. As just shown, the latter timescale is

\[
t_{\text{GR}} \equiv \nu_{\text{GR}}^{-1} \approx \frac{\ell^2}{\pi \nu_{\text{GR}}^2} \approx \kappa N \nu_{\text{GR}}^{-1}.
\]  

(106)

The former timescale is the coherence time for VRR, equation \( \text{(94)} \):

\[
t_{\Omega} \approx \frac{M_*}{m} \frac{P}{\sqrt{N}}.
\]  

(107)

The condition \( t_{\Omega} > t_{\text{GR}} \) is then

\[
\frac{M_*}{m} \frac{P}{\sqrt{N}} > \kappa N \nu_{\text{GR}}^{-1}
\]  

(108)

or

\[
\frac{a}{r_{\text{Schw}}} \sqrt{N} > \frac{M_*}{m}.
\]  

(109)

Applying this to the center of the Milky Way, the condition becomes

\[
\frac{a}{\text{mpc}} \sqrt{N(a)} > 10^2
\]  

(110)

which is likely to be satisfied beyond a few mpc from SgrA*.

On timescales longer than \( t_{\text{coh}} \), the torques driving RR will change direction. This is roughly equivalent in our simple model to changing the orientation of the triaxial ellipsoid, or to changing \( \ell_0 \) at fixed \( \ell \). Such changes might induce an orbit to evolve to values of \( \ell \) lower than \( \ell_{\text{min}} \), by advancing down the narrow “neck” in the lower left portion of Figure 13. However such evolution would be disfavored, for two reasons: (1) it would require a series of correlated changes in the background potential, increasingly so as \( \ell \) became small; (2) as \( \ell \) decreased and \( \nu_{\text{GR}} \) increased, changes in the background potential would occur on timescales progressively longer than the GR precession time, and adiabatic invariance would tend to preserve \( \ell \) (§4.4). These predictions can in principle be tested via direct N-body integration of small-N systems including post-Newtonian accelerations (e.g. Merritt et al. 2010).

A lower limit to the angular momentum for orbits near a massive BH could have important implications for the rate of gravitational wave events due to extreme-mass-ratio inspirals, or EMRIs (Hils & Bender 1995). The critical eccentricity at which the orbit evolution of a 10M_⊙ compact object begins to be dominated by gravitational wave emission is

\[
1 - e_{\text{EMRI}} \approx 10^{-5} \left( \frac{t_r}{10^9 \text{yr}} \right)^{-2/3} \left( \frac{M_*}{10^8 M_\odot} \right)^{4/3}
\]  

(111)

with \( t_r \) the relaxation time (e.g. Amaro-Seoane et al. 2007, eq. (6)). By comparison, equation \( \text{(102)} \), after substitution of \( N(< a) = N_0(a/\text{mpc}) \) implies

\[
1 - e_{\text{max}} \approx 2 \times 10^{-4} \left( \frac{M_*}{10^6 M_\odot} \right)^4 \left( \frac{N_0}{100} \right)^{-1} \left( \frac{a}{10 \text{mpc}} \right)^{-3}
\]  

(112)

9. ESTIMATES FOR REAL GALAXIES

In this section we estimate the fraction and lifetime of pyramid orbits to be expected in the nuclei of real galaxies.

We restrict calculations to the case of “maximal triaxiality,” \( e_b = e_c/2 \), although we leave the amplitudes of \( e_b, e_c \) free parameters. We also limit the discussion to orbits within the BH influence radius, \( r < r_{\text{inf}} \), where our analysis is valid and where orbits are typically regular.\footnote{Beyond \( r_{\text{inf}} \), centrifugal (mostly chaotic) orbits still exist and could dominate, e.g., the rate of feeding of a central BH. Merritt & Poor 2004.}

The first set of parameters is chosen to describe the center of the Milky Way. The BH mass is set to \( M_* = 4 \times 10^6 M_\odot \) (Ghez et al. 2008, Gillessen et al. 2009a,b). The density of the spherically symmetric stellar cusp is taken to be \( \rho_c = 1.5 \times 10^6 M_\odot \text{pc}^{-3} (r/1 \text{ pc})^{-\gamma} \) (Schödel et al. 2007), with \( \gamma = 1.5 \) (Schödel et al. 2008); the corresponding BH influence radius is \( r_{\text{inf}} \approx 3 \text{ pc} \). The triaxial component of the potential is highly uncertain: one source would be the nuclear bar with density \( \rho_b \approx 150 M_\odot \text{pc}^{-3} \) (Rodriguez-Fernandez & Combes 2008), yielding a triaxiality coefficient at \( r = 1 \text{ pc} \) of \( e_c \approx 10^{-3} \). We also considered a larger value, \( e_c = 10^{-2} \), which may be justified by some kind of asymmetry on spatial scales closer to \( r_{\text{inf}} \) than the bar. In this model, the precession time due to the spherical component of the potential, \( 2\pi/(3\dot{\nu}_{\text{GR}}) \) for a circular orbit, is independent of radius and equals \( \sim 1.7 \times 10^5 \text{ yr} \); the two-body relaxation time is also constant \( (5 \times 10^9 \text{ yr}) \), and timescales for scalar and vector resonant relaxation are given by equation \( \text{(93)} \), \( \text{(92)} \) with stellar mass \( m = 1 M_\odot \).

The second set of parameters is intended to describe the case of galaxies with more massive BHs, using the so-called \( M_* - \sigma \) relation in the form

\[
M_* \approx 1.7 \times 10^8 M_\odot \left( \frac{\sigma}{200 \text{ km s}^{-1}} \right)^{4.86}
\]  

(113)

Ferrarese & Ford 2003.\footnote{Combined with the definition of \( r_{\text{inf}} \approx GM_*/\sigma^2 \), we get

\[
 r_{\text{inf}} \approx 13 \text{ pc} \left( \frac{M_*}{10^8 M_\odot} \right)^{0.59}
\]  

(114)}

The two-body relaxation time evaluated at \( r_{\text{inf}} \) (assuming a mean-square stellar mass \( m_* = 1 M_\odot \) and a Coulomb logarithm \( \ln \Lambda = 15 \)) is

\[
t_{2\text{br}}(r_{\text{inf}}) \approx 2.1 \times 10^{13} \text{ yr} \left( \frac{\sigma}{200 \text{ km s}^{-1}} \right)^{7.5}
\]  

(115a)

\[
\approx 9.6 \times 10^{12} \text{ yr} \left( \frac{M_*}{10^8 M_\odot} \right)^{1.54}
\]  

(115b)

\text{8} Excepting for the effects of GR, which as noted above may introduce chaotic behavior even for orbit-averaged parameters. The chaos that sets in at \( r \gtrsim r_{\text{inf}} \) ([8]) arises from the coupling of the orbit-averaged and radial motions.

\text{9} These cusp parameters correspond to an inward extrapolation of the density observed at \( r > 1 \text{ pc} \). Recent observations (Reid et al. 2004, Do et al. 2009, Barrio et al. 2010) reveal a “hole” in the density of evolved stars inside \( \sim 0.5 \text{ pc} \), implying a possibly much lower density for the spherical component near the BH.
the flux in the full loss cone regime, 

\[ t_{\text{drain}} = \frac{1}{\mathcal{F} \nu_p} \approx \frac{5\pi}{3\Theta(GM_\bullet)^{3/2}} \frac{a^{5/2}}{\epsilon_c(a)} \]

\[ \approx 10^9 \text{ yr} \times \frac{\epsilon_c(a)}{10^6 M_\odot} - \frac{a}{1 \text{ pc}}^{5/2} \]

A more exact calculation of \( t_{\text{drain}}(a) \) for the Milky Way, based on numerical analysis of properties of orbits sampled from the entire phase space, is shown in Figure 15.

Finally, we estimate the total capture rate for all pyramids inside \( r_{\text{inf}} \), using \( t_{\text{pyr}} \equiv t_{\text{drain}}(r_{\text{inf}}) \) as a typical timescale and applying (113, 114, 117):

\[ t_{\text{pyr}} \approx 6 \times 10^{11} \text{ yr} \times \frac{\epsilon_c(r_{\text{inf}})}{10^6 M_\odot} - 0.025 \]

The capture rate from pyramids is then

\[ M_{\text{pyr}} \approx \epsilon_c(r_{\text{inf}}) M_\bullet \approx 1.6 \times 10^{-4} M_\odot \ yr^{-1} \Theta \left( \frac{M_\bullet}{10^6 M_\odot} \right)^{1.025} \]

\[ (119) \]

For the Milky Way we find \( \sim 4 \times 10^{-5} M_\odot \ yr^{-1} \) for \( \epsilon_c = 10^{-3} \) and \( \sim 10^{-4} M_\odot \ yr^{-1} \) for \( \epsilon_c = 10^{-2} \).

This capture rate should be compared with that due to two-body relaxation, which is estimated to be (Merritt 2009)

\[ M_{\text{2br}} \approx 0.1 \frac{M_\bullet}{t_{\text{2br}}} \approx 10^{-6} M_\odot \ yr^{-1} \times \left( \frac{M_\bullet}{10^6 M_\odot} \right)^{-0.54} \]

\[ (120) \]

Thus even for a Milky Way-sized galaxy, the capture rate of pyramids could be comparable with or greater than that due to two-body relaxation. For more massive galaxies this inequality becomes even stronger. However, this is only the initial capture rate – after \( \sim t_{\text{pyr}} \), all stars on pyramid orbits would have been consumed, at least in the absence of other mechanisms for repopulating the small-\( \ell \) parts of phase space (not necessarily \( \ell \lesssim \ell_0 \), but the much broader region \( \ell \lesssim \sqrt{\epsilon_c} \) from which draining is effective).

In the most luminous galaxies, like M87, standard mechanisms for relaxation are expected to be ineffective even over Gyr timescales and pyramid orbits once depleted are likely to stay depleted. Setting \( \epsilon_c = 0.1, \Theta = 3 \) and \( M_\bullet = 4 \times 10^6 M_\odot \) gives for M87 \( t_{\text{pyr}} \approx 5 \) Gyr and \( M_{\text{pyr}} \approx 4 \times 10^5 M_\odot \). This could be an effective mechanism for creating a low-density core at the centers of giant elliptical galaxies.

10 CONCLUSIONS

We discussed the character of orbits within the radius of influence \( r_{\text{inf}} \) of a supermassive BH at the center of a triaxial star cluster. The motion can be described as a perturbation of Keplerian motion; we derive the orbit-averaged equations and explore their solutions both analytically (when the triaxiality is small) and numerically. Orbits are found to be mainly regular in this region. There exist three families of tube orbits; a fourth orbital family, the pyramids, can be described as eccentric Keplerian ellipses that librate in two directions about

---

**Fig. 15.** Various timescales for Milky Way center. Green and blue solid curves are the pyramid draining times (more exact calculation than equation (117) for \( \epsilon_c = 10^{-2} \) and \( 10^{-3} \), dotted green and blue curves denote typical orbital plane precession timescales \( \nu_{\Omega}^{-1} \) for low-\( \ell \) orbits (\( \ell^2 \approx \epsilon(a) \)); Newtonian and relativistic timescales are given for circular orbits; other timescales are marked on the plot. Vector resonant relaxation is suppressed when \( t_{\text{RR},\nu} \gtrsim \nu_{\Omega}^{-1} \) (marked by conversion of line into dashed). (Merritt et al. 2007).

We first estimate the radius \( r_{\text{crit}} \) that separates the empty (\( q < 1 \)) and full loss cone regimes. As noted in the previous section, GR precession prevents a pyramid orbit from reaching arbitrarily low angular momenta; the radius beyond which capture becomes possible is roughly \( r_{\text{crit}} \). Using equation (60) with \( W = (15 \epsilon)^{2} \) (the maximum for pyramids) and equations (13a), (14), the condition \( q = 1 \) translates to

\[ 1 = \frac{4\pi}{3 - \gamma} \frac{\rho \sigma^3}{M_\bullet} \left( \frac{r_{\text{crit}}}{r_0} \right)^{3 - \gamma} 2\Omega' \frac{5\pi}{3(2 - \gamma)} \frac{\epsilon_c(r_{\text{crit}})}{\sqrt{\Theta \Sigma_{\text{Schw}} / r_{\text{crit}}}} \]

If we take \( r_0 \) to be \( r_{\text{inf}} \), and \( \rho \) and \( \sigma \) as the density and velocity dispersion at this radius, we obtain

\[ r_{\text{crit}} \approx 0.5 \left( \frac{\sigma}{c} \right)^{2/7} \left( \frac{\epsilon_c(r_{\text{inf}})}{\epsilon_c} \right)^{2/7} \]

The radius \( r_{\text{crit}} \) typically lies in the range (0.2 – 0.7)\( r_{\text{inf}} \), weakly dependent on the parameters. Since regular pyramid orbits exist only for \( a \lesssim r_{\text{inf}} \) (Figure 10), there is evidently a fairly narrow range of radii for which capture of stars from pyramid orbits is possible. However pyramid-like, centripetal motions can exist at much larger radii (Poon & Merritt 2003).

Next we make a rough estimate of the pyramid draining time at \( a > r_{\text{crit}} \), using the expression (60a) for the flux in the full loss cone regime, \( \mathcal{F} = \mu / (P \nu_p) \); \( \mu \)

---

This is also roughly the radial range from which extreme-mass-ratio inspiral events are believed to originate; (e.g. Ivanov 2002).
the short axis of the triaxial figure. At the “corners” of the pyramid, the angular momentum reaches zero, which means that stars on these orbits can be captured by the BH. We derive expressions for the rate at which stars on pyramid orbits would be lost to the BH; there are many similarities with the more standard case of diffusional loss cone refilling, but also some important differences, due to the fact that the approach to the loss cone is deterministic for the pyramids, rather than statistical.

The inclusion of general relativistic precession is shown to impose a lower bound on the angular momentum. We argue that a similar lower bound should apply to orbital evolution in the case that the torques are due to resonant relaxation. The rate of consumption of stars from pyramid orbits is likely to be substantially greater than the rate due to two-body relaxation in the most luminous galaxies, although in the absence of mechanisms for orbital repopulation, these high consumption rates would only be maintained until such a time as the pyramid orbits have been drained; however the latter time can be measured in billions of years.

We thank T. Alexander, S. Hughes, A. Rasskazov and B. Kocsis for fruitful discussions. DM was supported by grants AST-0807910 (NSF) and NNX07AH15G (NASA). EV acknowledges support from Russian Ministry of science and education (grants No.2009-1.1-126-056 and P1336).
