(Dated: July 27, 2013)

We develop a technique, denoted as the finite radius approximation (FRA), that uses a two-dimensional version of the Shannon-Nyquist sampling theorem to determine transverse densities and their uncertainties from experimental quantities. Uncertainties arising from experimental uncertainties on the form factors and lack of measured data at high \( Q^2 \) are treated. A key feature of the FRA is that a form factor measured at a given value of \( Q^2 \) is related to a definite region in coordinate space. An exact relation between the FRA and the use of a Bessel series is derived.

The proton Dirac form factor is well enough known such that the transverse charge density is very accurately known except for transverse separations \( b \) less than about 0.1 fm. The Pauli form factor is well known to \( Q^2 \) of about 10 GeV\(^2\), and this allows a reasonable, but improvable, determination of the anomalous magnetic moment density.

Keywords: electromagnetic form factors, transverse momentum distributions, generalized parton distributions

I. INTRODUCTION

A truly impressive level of experimental technique, effort and ingenuity has been applied to measuring the electromagnetic form factors of the proton, neutron (nucleon) and pion [1–6]. These quantities are probability amplitudes that a given hadron can absorb a specific amount of momentum and remain in the ground state, and therefore should supply information about charge and magnetization spatial densities.

The text-book interpretation of these form factors is that their Fourier transforms are measurements of the charge and magnetization densities. This interpretation is deeply buried in the thinking of nuclear physicists and continues to guide intuition, as it has since the days of the Nobel prize-winning work of Hofstadter[7]. Nevertheless, the relativistic motion of the constituents of the system causes the text-book interpretation to be incorrect[8].

The difficulty is that in electron-proton scattering the initial and final nucleon states have different momenta and therefore different wave functions. In general, these different states are related by a boost operator that depends on the full complexity of QCD. The use of transverse densities [9, 10] avoids this difficulty by working in the infinite momentum frame and taking the space-like momentum transfer to be in the direction transverse to that of the infinite momentum. In this case, the different momenta of the initial and final nucleon states are accommodated by using two-dimensional Fourier transforms. The transverse charge and magnetization densities are constructed from density operators that are the absolute square of quark-field operators, so they are correctly defined as densities.

But there also is a more general context, with the high current interest in mapping the three-dimensional structure of the nucleon [11]. Therefore we also aim to provide a technique that can be easily extended determining the spatial aspects of other quantities related to transverse momentum distributions and generalized parton distributions.

Next we present an overview of the remainder of
with the azimuthal symmetry of the Lorentz invariant form of \( F(Q^2) \), and that \( \rho(b) \) is localized, \( \rho(b) = 0 \) for \( b \) greater than some finite distance. The function \( \rho(b) \) is band limited and can be written as discrete Fourier series involving \( F(Q^2) \). This result, known as the Nyquist-Shannon sampling theorem, enables us to associate the density at a given range of values of \( b \) with a discrete value of the momentum transfer, see Eq. (3) below (which we denote as the finite radius approximation FRA). The equivalence between the FRA and the Bessel series expansion technique is also established. A general version of the FRA, applicable to other observable quantities, is also presented.

Sect. [III] concerned with exploring the validity and utility (which depends on the number of terms needed in the discrete Fourier series) of the FRA using examples in which the form factor is given by a monopole (M) or dipole (D) form. Sect. [V] is concerned with the reality that the proton electromagnetic form factors are not known as analytic functions. Instead, form factors \( G_{E,M}, F_{1,2} \) (with uncertainties) measured at discrete values of \( Q^2 \) up to a finite maximum value \( Q^2_{\text{max}} \) are known. This means that \( \rho \) is known only within some uncertainties, and a technique to determine the uncertainties in \( \rho \) must be developed. This is accomplished by using the values of \( F \) at \( b \) in the FRA. Estimates of the effects of incompleteness, arising from contributions in the unmeasured region, \( Q^2 > Q^2_{\text{max}} \), are also provided. The paper is concluded with a brief summary.

II. GENERAL CONSIDERATIONS

Intuitively, we expect particles to be localized. That is, we expect densities associated with the particle to be well approximated by functions that are zero outside some maximum radius. This assumption, called the finite radius approximation (FRA), greatly simplifies the relationship between form factors and their associated densities.

Let \( \rho(b) \) be a two-dimensional transverse density function (we later take this to be charge or magnetization density) and let \( F(Q^2) \) be the associated form factor. The transverse density is given by [8, 13]

\[
\rho(b) = \frac{1}{(2\pi)^2} \int d^2 q e^{-iq b} F(Q^2 = q^2) = \frac{1}{2\pi} \int QdQ J_0(Qb)F(Q^2), \tag{1}
\]

with the azimuthal symmetry of \( \rho \) obtained from the Lorentz invariant form of \( F \) in the space-like region with \( q^+ = 0 \). If one knows \( F(Q^2) \) exactly for all values of \( Q^2 \), the transverse density is known immediately. However, one only knows \( F(Q^2) \) within experimental uncertainties for a finite range of \( Q^2 \). This means that \( \rho \) is known only within some uncertainties, and it is necessary to develop a technique to determine the uncertainties in \( \rho \).

We proceed by assuming that \( \rho(b) \approx 0 \) for \( b \geq R \), where \( R \) is a finite distance. Since the functions \( \rho, F \) are Fourier transforms, \( F \) is band-limited. We proceed in the spirit of the Nyquist-Shannon sampling theorem. The function \( \rho \) can be expanded as

\[
\rho(b) = \sum_{n=1}^{\infty} c_n J_0(X_n b/R), \tag{2}
\]

where \( X_n \) is the \( n \)-th zero of \( J_0 \), and \( c_n \) is given approximately by the formula

\[
c_n \approx \tilde{c}_n = \frac{1}{2\pi R^2 J_1(X_n)^2} F(Q_n^2), \tag{3}
\]

with

\[
Q_n = \frac{X_n}{R}. \tag{4}
\]

The above equation Eq. (3), which is the two-dimensional version of [12], is the central formal result of this paper. Using this in Eq. (2) yields the following expression for \( \rho(b) \):

\[
\rho(b) = \frac{1}{\pi R^2} \sum_{n=1}^{\infty} J_1(X_n)^{-2} F(Q_n^2) J_0(X_n b/R), \tag{5}
\]

The result Eq. (5) is the central phenomenological result because it tells us that measuring a form factor at \( Q_n^2 \) provides information about the density mainly at values of \( b < R/X_n \). This is because Bessel functions are of the order of unity only for values of arguments less than that of its first zero.

A. Equivalence with the Bessel Series

Replacing \( c_n \) by \( \tilde{c}_n \) would be exact if the assumption \( \rho(b \geq R) = 0 \) is exactly true. This condition is clearly approximately true, so we expect a near equality between \( c_n \) and \( \tilde{c}_n \). In fact, it turns out that the approximation is amazingly accurate as we now demonstrate. Numerical examples are provided in subsequent sections. The exact values of \( c_n \) are obtained from the orthogonality of the cylindrical Bessel functions as

\[
c_n = \frac{2}{R^2 J_1(X_n)^2} \int_0^R b \rho(b) J_0(X_n b/R) db. \tag{6}
\]
The use of this in Eq. 11 followed by integration over $b$ can be done using a standard identity to yield

$$c_n = \frac{X_n}{\pi R^2 J_1(X_n)} \int_0^\infty \frac{q F(q^2) J_0(qR)}{(\frac{X_n^2}{R^2} - q^2)} dq. \quad (7)$$

We may use a dispersion relation for the form factor \[14\] to establish the connection between $\tilde{c}_n$ and $c_n$. First recall that, for $Q^2 > 0$,

$$F(Q^2) = \frac{1}{\pi} \int_{4m^2}^\infty dt \frac{Im F(-t)}{t + Q^2}. \quad (8)$$

and that using this expression in Eq. (1) yields

$$\rho(b) = \frac{1}{2\pi^2} \int_{4m^2}^\infty dt K_0(\sqrt{b}t) Im F(-t). \quad (9)$$

Proceed by using the above in Eq. 8 and then integrate over $b$ using:

$$\int_0^R b db K_0(\sqrt{b}) J_0\left(\frac{X_n}{R}\right) = \frac{1}{\pi R^2} \times \left[1 + X_n J_1(X_n) K_0(\sqrt{t}R)\right]. \quad (10)$$

Then,

$$c_n = \frac{1}{R^2 J_1(X_n) \pi^2} \int_{4m^2}^\infty dt \frac{Im F(-t)}{t + \frac{X_n^2}{R^2}} \times \left[1 + X_n J_1(X_n) K_0(\sqrt{t}R)\right]. \quad (11)$$

Using only the first term within the brackets along with Eq. 8 allows one to identify the integral over $t$ as $\pi F(Q_n^2)$. Thus (using Eq. 8) one arrives at the result that $c_n = \tilde{c}_n$ plus a correction term, suppressed by a modified Bessel function evaluated at a large argument. For example, a significant contribution to the $Im F$ comes from the region $t \sim m_\rho^2 = 0.5$ GeV$^2$, and using $R = 3.3$ fm (see Sec. III), then $K_0(m_\rho R) = 10^{-6}$. The net result is that

$$c_n = \tilde{c}_n + \delta_n = \frac{X_n R^2 J_1(X_n)}{J_1(X_n) \pi^2} \int_{4m^2}^\infty dt \frac{Im F(-t)}{t + \frac{X_n^2}{R^2}} K_0(\sqrt{t}R). \quad (12)$$

A reasonable estimate is that

$$\frac{c_n - \tilde{c}_n}{\tilde{c}_n} \sim X_n J_1(X_n) 10^{-6}. \quad (13)$$

The condition that $\delta_n$ be small is that $R$ be chosen to be large enough. We ensure that this condition is well-satisfied for all of our examples and applications.

### B. Preliminary Evaluations

It is worthwhile to perform some preliminary analysis of the expression Eq. 11. For $x \gg 1$, $J_0(x)$ is well approximated \[15\] by

$$J_0(x) \approx \sqrt{\frac{2}{\pi x}} \cos(x - \frac{\pi}{4}) \quad (14)$$

so that the $n$’th zero of $J_0$, $X_n$, is given approximately by

$$X_n \approx (n + \frac{3}{4}) \pi \quad (15)$$

and

$$J_1(X_n) = -J_0'(X_n) \approx (-1)^n 2^{-1/2} \pi^{-1}(n + \frac{3}{4})^{-1/2}. \quad (16)$$

It follows that for large $n$, the terms in the series Eq. 5 for $\rho(b)$ are of the form:

$$\frac{\pi}{2R^2} (n + \frac{3}{4}) F(Q_n^2) J_0(X_n) b \sim n F((\frac{n\pi}{R})^2)$$

at $b = 0$. So for the series to converge everywhere, namely at $b=0$, we need $F$ to fall faster than $Q^{-2}$ for large $Q$. The oscillations of the cylindrical Bessel functions hastens the convergence for non-zero values of $b$.

Given this convergence, the function $\rho(b)$ can be approximated by using a finite number of terms in the series Eq. 5. Because $Q_n^2 = (X_n/R)^2$ serves as the $Q^2$ in the argument of $F$, cutting off the series at $N$ terms is equivalent to taking $F(Q^2) = 0$ for $Q^2 > (X_N/R)^2$.

If the assumption that $\rho(b) = 0$ for $b \geq R$ holds for a given value of $R$, then it also holds for larger values of $R$. We can see from Eq. 5 that increasing $R$ increases the frequency with which $F(Q^2)$ is sampled and therefore decreases the range that is sampled. As a consequence, an increase in $R$ demands an increase in the number of terms in the approximation for $\rho$.

A quick result following from the fact that $\rho$ is the Fourier transform of $F$ is that the mean-square-radius $(b^2)$ is given by

$$\langle b^2 \rangle \equiv \int d^2 b \ b^2 \rho(b) = -4 \frac{d \log F}{dQ^2} \bigg|_{Q^2=0}. \quad (17)$$

In this paper, we choose $R \approx 5\sqrt{\langle |b^2| \rangle}$ in determining the number of terms in our expansion. Numerical studies of the form factors considered in preparing
this paper have shown that this value of \( R \) is sufficiently large so that perturbations to this value lead to the same density functions and that \( R^2 \rho(R) \) is always small enough so that the difference between \( c_n \) and \( \bar{c}_n \) is minute.

\[ \rho^{(\lambda)}(b) = \frac{1}{2\pi} \int QdQ J_\lambda(Qb) F^{(\lambda)}(Q^2). \]  
(18)

An example, discussed in detail in Sect. IV.C is the magnetization density \( \rho_m \) of the anomalous magnetic moment. We expect that the index \( \lambda \) is associated with a given number of units of orbital angular momentum. Extracting \( \rho^{(\lambda)}(b) \) is facilitated by using the expansion

\[ \rho^{(\lambda)}(b) = \sum_{n=1}^{\infty} c_n \lambda J_\lambda(X_{\lambda,n} b/R), \]  
(19)

where \( X_{\lambda,n} \) is the \( n \)th zero of the Bessel function of order \( \lambda \). Then the sampling theorem leads immediately to the result.

\[ c_n \lambda \approx \tilde{c}_n \lambda \approx \frac{2}{R^2} J_{\lambda+1}(X_{\lambda,n})^2 F^{(\lambda)}(Q^2_{\lambda,n}), \]  
(20)

\[ Q_{\lambda,n} = \frac{X_{\lambda,n}}{R}. \]

The difference between \( c_n \lambda \) and \( \tilde{c}_n \lambda \) can be shown to be very small by using the arguments of Sect. II.A.

The result Eq. (20) can be used to relate accessible kinematic ranges with transverse regions.

C. Other transverse densities

We believe that the techniques used in this paper can be exploited to image other quantities that depend on transverse position. Suppose there is a transverse quantity \( \rho^{(\lambda)}(b) \) that is a two-dimensional Fourier transform of an experimental observable \( F^{(\lambda)}(Q^2) \) such that

Then the associated charge density is obtained from Eq. (1):

\[ \rho_M(b) = \frac{1}{2\pi} \Omega^2 K_0(\Omega b). \]  
(22)

This function diverges as \( \log(1/b) \) for small values of \( b \) and so provides a severe test of the method. With the stated value of \( \Omega \) we find \( (b^2 M)_M = 4/\Omega^2 = 0.26 \text{ fm}^2 \), and thus take \( R = 5\sqrt{|\langle b^2 \rangle|} = 2.56 \text{ fm} \). We then find the fractional difference between \( c_n \) and \( \bar{c}_n \) of Eq. (12) is less than \( 5 \times 10^{-4} \) for small values of \( n \), and the magnitude decreases rapidly as \( n \) increases.

We compare to \( \rho_M \) to its approximation as an expansion in \( N \) terms, with \( N = 10, 20, 50 \) in Fig. 1. We see that our approximations differ from the exact result, but the difference decreases with increasing value of \( N \). The 50 term approximation works reasonably well for all value of \( b \) for which the density differs appreciably from 0. Unfortunately the 10, 20 and 50 term approximations would require measurements at \( Q^2 = 6.23 \) and \( 144 \text{ GeV}^2 \). Only the first value seems presently achievable.

We now examine the dipole form factor given by

\[ F_D(Q^2) = \frac{1}{(1 + Q^2/\Lambda^2)^2} \]  
(23)

where \( \Lambda^2 = 0.71 \text{ GeV}^2 \). This value is suggested by its historically close relationship with the proton electromagnetic form factors. The dipole transverse charge density is obtained by from Eq. (1) to be

\[ \rho_D(b) = \frac{1}{4\pi} b \Lambda^3 K_1(b\Lambda). \]  
(24)

This form factor falls more rapidly with increasing \( Q^2 \) than does \( F_M \), and also corresponds to the larger
physical extent of the proton as compared to the pion. Furthermore, $\rho_D$ is not singular at the origin ($\sim 1 - 0.058 (b\Lambda)^2$). Thus there are several reasons to expect to find better convergence properties, and therefore a more accurate representation of the transverse density for the proton. With this value of $\Lambda$, $\langle b^2 \rangle = 8/\Lambda^2 = 0.439$ fm$^2$, and $R = 3.31$ fm. Once again the fractional difference of Eq. (12) is truly tiny for all values of $n$: the fractional differences are less than about $10^{-5}$ for all values of $n$ that correspond to non-zero $c_n$. We plot $\rho_D$ and its approximations in Fig. 2.

We can see how the approximations converge to the exact $\rho_D$. Even the 10 term approximation is reasonably good and the 15 term approximation is extremely accurate except for $b < 0.1$ fm.

Another way of looking at convergence properties is to examine properties of the transverse density. We display upper limit dependence of $\langle b^2 \rangle_{M,D}$ for both the monopole and dipole form factors. We compute these matrix elements for a range of values of $b$ from 0 to 1.5 fm. This covers the region up to where $\rho$ is about 0.1% of its central value. The results are shown in Table I. Despite the relatively poor convergence obtained for the monopole form factor (Fig. 1), reasonable convergence for the expectation value is obtained. However, the convergence is much better for the dipole form factors. The 5,10 and 15 term approximations correspond to values of $Q^2 = 0.9, 4$ and 9 GeV$^2$. These values and even higher have already been achieved experimentally. Thus we reasonably expect that the proton transverse density is now known. Indeed, this has already been suggested [8]. However, now we can answer the question: “How well is the proton transverse charge density known?”.

TABLE I: Upper limit, $N$, dependence of $\langle b^2 \rangle_{M,D}$ computed for values of $b$ from 0 to 1.5 fm.

IV. EXTRACTION OF PROTON FORM FACTORS AND UNCERTAINTIES

The transverse densities we seek are given in terms of the Dirac $F_1$ and Pauli $F_2$ form factors, which are expressed in terms of the Sachs electromagnetic form factors $G_E$ and $G_M$ as

$$F_1(Q^2) = \frac{G_E + \tau G_M}{1 + \tau}, F_2(Q^2) = \frac{G_M - G_E}{1 + \tau}, \quad (25)$$

where $\tau = Q^2/M^2$.

Elastic electron-proton scattering has been measured up to $Q^2$ of about 30 GeV$^2$, with the separation of both $G_E$ and $G_M$ extracted using a variety of techniques up to 10 GeV$^2$. There are two sources of uncertainty in the extraction of the transverse densities. Experimental uncertainties from the measurements of $G_E$ and $G_M$ yield uncertainty in the extracted densities, and incompleteness error arise from the lack of form factor measurements at very high $Q^2$ (above 30 GeV$^2$). In this section, we perform extractions of the transverse density and evaluate the the effects that two kinds of uncertainties on the densities.

The form factors $G_E$ and $G_M$ have been extracted from a global analysis of the world’s cross section and polarization data, including corrections for two-photon exchange corrections from Ref. [16]. The analysis is largely identical to that of Ref. [17], although additional high $Q^2$ form factor results [18] have been included. In addition, the slopes of $G_E$ and $G_M$ at $Q^2=0$ were constrained in the global fit based on a dedicated analysis of the low $Q^2$ data. In the global fit, the large body of high $Q^2$ data, especially for $G_M$, can constrain the fit well enough that the low $Q^2$ behavior is not primarily constrained by the low $Q^2$ data. Constraining the slope based on an analysis of only the low $Q^2$ data keeps the global fit from doing a poor job at low $Q^2$ simply to make a slight improvement in the high $Q^2$ data. In writing $G_E(Q^2) = 1 - Q^2 R_E^2/6$, the value of $R_E$ was constrained to be 0.878 fm and $R_M$ was constrained to
be 0.860 fm. This is important in the extraction of the large scale structure of the density. The fit is of the following form:

\[ G_M(Q^2) = \mu_p \frac{1 + p_6 \tau + p_{10} \tau^2 + p_{14} \tau^3}{1 + p_2 \tau + p_4 \tau^2 + p_8 \tau^3 + p_{12} \tau^4 + p_{16} \tau^5} \]

\[ G_E(Q^2) = \frac{1 + q_2 \tau + q_4 \tau^2 + q_8 \tau^3 + q_{12} \tau^4 + q_{16} \tau^5}{1 + q_6 \tau + q_{10} \tau^2 + q_{14} \tau^3} \]

(26)

where the fitting constants \( p_2, \ldots, p_{16}, q_2, \ldots, q_{16} \) are given in Table II and we use \( \mu_p = 2.792782 \).

</table>

We also need a reliable estimate of the experimental uncertainties in the form factors, in order to determine the uncertainty in the extracted coefficients \( c_n \). In the global analysis, there are two sources that can contribute to the uncertainties in \( G_E \) and \( G_M \): the uncertainty on each individual cross section or polarization ratio, and the normalization uncertainty associated with each cross section data set. The normalization factors are allowed to vary in the fit, as was the case in Ref. [17]. To estimate the uncertainty in the fitted normalization factors, we take the normalization factor from a single data set and vary it around its best fit value (while allowing all other parameters to vary) to map out the change in the \( \chi^2 \) of the fit as a function of the normalization factor. This yields uncertainties between 0.2% and 2.5% (typically 0.6%–1%), compared to the initially quoted uncertainties of 1.5% to 5%, for the data before the normalization has been constrained by the fit. However, by assuming that all uncertainties are entirely uncorrelated or pure normalization factors, we neglect the possibility there may be some angle-dependent or \( Q^2 \)-dependent correction that could bias the determination of the relative normalization coefficients. Thus, we assume that the final uncertainty on each normalization factor is at least 0.5%, even if the result of the \( \chi^2 \) analysis yields a smaller result.

Having the uncorrelated uncertainties for each data point and the constrained normalization uncertainties, we then extract the uncertainties for \( G_E \) and \( G_M \). For the uncorrelated uncertainties, we randomly shift each cross section and polarization ratio measurement within its uncertainties, and then redo the fit for \( G_E \) and \( G_M \). We repeat this 1000 times, and look at the range of values for several \( Q^2 \) values (55 \( Q^2 \) values between 0.007 and 31.2 GeV\(^2\)). This yields our uncertainty at each of the \( Q^2 \) points. To obtain the impact of the normalization uncertainties, we repeat this procedure, varying the normalization of each cross section data set according to its uncertainty, and determine the range of \( G_E, G_M \) values for the same set of \( Q^2 \) points. In this procedure, the uncertainty obtained depends on the fit function used, and a functional form with insufficient flexibility will yield significant smoothing of the results and thus unrealistically small uncertainties. We scale up our uncertainties by a factor of two, which yields good agreement with best direct measurements of the form factors and uncertainties.

As mentioned above, we use the electric and magnetic radii extracted from just the low \( Q^2 \) data in as a constraint to the global fit, which can yield unrealistically small uncertainties for below \( Q^2 = 0.2 \) GeV\(^2\), especially for \( G_M \), where the very low \( Q^2 \) data is extremely limited. Thus, for these low \( Q^2 \) values, we calculate the uncertainty at each \( Q^2 \) corresponding to the uncertainty in the extracted radius, assuming the linear expansion. We take this larger uncertainty, rather than the result from the fit, until the uncertainties from direct extractions of the form factors are of comparable size, at which point we take the direct extraction of the uncertainty. For \( Q^2 > 10 \) GeV\(^2\), there are no direct extractions of \( G_E \), and thus we again have to be sure that we do not underestimate the uncertainties. The global fit yields \( G_E/G_D \approx 0 \) at high \( Q^2 \), but it is difficult to tell if \( G_E \) becomes zero, or if \( G_E/G_M \) continues its linear decrease with \( Q^2 \) [18]. Thus, for \( Q^2 > 10 \) GeV\(^2\), we set the uncertainty to be the difference between the best fit, which yields \( G_E \approx 0 \) and the fit where the linear falloff in \( G_E/G_M \) continues, with \( G_E \) changing sign and then increasing in absolute value.

We then use the fit and uncertainties for \( G_E \) and \( G_M \) to extract \( F_1 \) and \( F_2 \), treating the uncertainties in \( G_E \) and \( G_M \) as uncorrelated, yielding:

\[ (dF_1)^2 = \left( \frac{1}{1 + \tau} \right)^2 (dG_E)^2 + \left( \frac{\tau}{1 + \tau} \right)^2 (dG_M)^2 \]  

(27)

\[ (dF_2)^2 = \left( \frac{1}{1 + \tau} \right)^2 (dG_E)^2 + \left( \frac{1}{1 + \tau} \right)^2 (dG_M)^2 \]  

(28)
While the Rosenbluth extractions yield a strong anticorrelation between the uncertainties on $G_E$ and $G_M$, the polarization ratio yields a correlated uncertainty; in the global fit, the combined result is fairly well approximated by entirely uncorrelated uncertainties. Figure 3 shows the extracted values of $F_1(Q^2)$ and $F_2(Q^2)$ and their error bands, scaled by a factor of $Q^4$.

We note that for $Q^2 < 0.5$, the uncertainty coming from cross section normalizations can be the larger contribution to the total uncertainty (and it’s dominant for $G_E$ below 0.1 GeV$^2$). While the normalization uncertainty in the cross sections won’t give a normalization style uncertainty on $G_E$, the normalization of a given experiment will tend to have a correlated effect on all of the extractions within the $Q^2$ covered by the experiment. This effect is accounted for by using the procedure discussed below in Sect. V.A.

V. EXTRACTION OF REALISTIC PROTON TRANSVERSE DENSITIES

The principle aim of this paper is to use data observed in experiments to obtain the charge and magnetization densities. Recall that the transverse charge density $\rho_{ch}$ is given by

$$\rho_{ch}(b) = \frac{1}{2\pi} \int Q dQ J_0(Qb) F_1(Q^2).$$  (29)

The two-dimensional Fourier transform of $F_2$, $\rho_2$ is similarly given by

$$\rho_2(b) = \frac{1}{2\pi} \int Q dQ J_0(Qb) F_2(Q^2).$$  (30)

However the true magnetization density, obtained by computing the expectation value of the transverse position operator with the electromagnetic current operator is given [10] by

$$\rho_m(b) = -\frac{b}{2\pi} \frac{d}{db} \rho_2(b) = \frac{b}{2\pi} \int Q^2 dQ J_1(Qb) F_2(Q^2).$$  (31)

This quantity is the density related to the anomalous magnetic moment. We begin by extracting $\rho_{ch,2}$. The starting point is to use the above expressions along with the experimentally determined $F_{1,2}$ obtained from the fits of Sect. IV. But extracting realistic transverse densities requires that a determination of the uncertainties in the results. There are two sources of uncertainty. Experimental data have uncertainties in the region where they are measured, and no direct information is available above some maximum value of $Q^2 = Q_{\text{max}}^2$, where there are no measurements. The experimental uncertainties lead directly to uncertainties in the $\tilde{c}_i$ via Eq. (3), and can be taken into account without further ado. However, uncertainty must arise because of lack of knowledge of form factors for $Q^2 > Q_{\text{max}}^2$, and these need to be estimated. This error is called the incompleteness error.

A. Impact of Experimental Uncertainties on the Extracted Transverse Densities

We first treat the experimental uncertainties. We only use the series Eq. (5) for values of $Q^2$ for which form factors have been extracted. The magnetic form factor $G_M$ is well measured up to $Q^2 = 31$ GeV$^2$, but $G_E$ is only known up to $\sim 10$ GeV$^2$. Based on the
estimated uncertainties on $G_F$ above 10 GeV², we find that while $F_1$ is relatively well measured up to 30 GeV², the uncertainties on $F_2$ grow rapidly above 10 GeV², reaching 25% by 13 GeV². These upper limits on $Q^2$ are related to limits on the summation index $n$ (of Eq. (3)) through Eq. (4) which requires values of $R_n$. Taking $\langle b^2 \rangle$ given by $\rho_{ch,2}$ from the fits presented above, we use Eq. (17) to obtain $\rho_{ch}(b)$ in Fig. 4. The densities peak at $b = 0$ and $R_1 = 3.29$ fm and $R_2 = 3.62$ fm for $F_1$. This corresponds to upper limits $N$ on the sum over $n$ $n = 30$, $Q_{20}^2 = 31$ GeV² for $\rho_{ch}(b)$, but only up to $n = 20$, $Q_{20}^2 = 11$ GeV² for $\rho_2(b)$.

Fig. 4: (Color Online) The transverse densities $\rho_{ch,\,2}$ (blue, solid) of the parameterizations and their approximates to 10 terms (red, long dash), 20 terms (green, medium dash), 30 terms (brown, short dash) and using the parameterization of Eq. (29). The approximations converge as the number of terms increases.

The transverse densities $\rho_{ch,\,2}$ are plotted as the solid curves in Fig. 4. The densities peak at $b = 0$ and that the transverse density $\rho_2$ has a slightly broader spatial extent than that of $\rho_{ch}$.

The next step is to extract $\bar{c}_n$ from the fit to the form factor using Eq. (3). The uncertainty on $F_{1,2}(Q^2)$ directly yields an uncertainty on $\bar{c}_n$, and thus its contribution to $\rho(b)$ (Eq. (2)). Assuming the errors from each $\bar{c}_n$ extraction add constructively, we obtain

$$\Delta_{\text{exp}} \rho_{ch}(b) = \sum_{n=1}^{30} \left| \frac{\partial \rho_{ch}(b)}{\partial F_1} \right| dF_1((X_n/R_1)^2)$$

$$= \frac{1}{\pi R_1^2} \sum_{n=1}^{30} J_1(X_n) - 2 \left| J_0(X_n) \frac{b}{R_1} \right| dF_1((X_n/R_1)^2),$$

(32)

$$\Delta_{\text{exp}} \rho_2(b) = \sum_{n=1}^{20} \left| \frac{\partial \rho_2(b)}{\partial F_2} \right| dF_2((X_n/R_2)^2)$$

$$= \frac{1}{\pi R_2^2} \sum_{n=1}^{20} J_1(X_n) - 2 \left| J_0(X_n) \frac{b}{R_2} \right| dF_2((X_n/R_2)^2).$$

(33)

Note that the errors are added linearly. This means that we are taking the worst case possible by assuming a full correlation. These uncertainties in densities are plotted in Fig. 5. They are about 1.5% of the transverse density at $b = 0$ and decrease (in absolute value) as the distance increases. The fractional uncertainty is small (below 10%) until $b \approx 1$ fm, where the density is only a few percent of the peak density.

B. Incompleteness Error

We next study the uncertainties in the transverse density caused by lack of experimental knowledge at large values of $Q^2$. The first step is to understand the meaning of the truncations made in Eq. (29) and Eq. (31). Plots of these approximations are given in Fig. 4. We see that for $\rho_2$, one achieves agreement with the parameterization for values of $N$ as
low as 20, with the largest disagreement at \( b = 0 \). For \( \rho_{ch}(b = 0) \), the difference between the result from the parameterization and the \( N = 30 \) approximation is -2\%, while for \( \rho_2(b = 0) \), the \( N = 20 \) approximation is only 1\% below the full result. Even though fewer terms are included in the approximation for \( F_2 \), the agreement is comparable, due to the more rapid fall-off of \( F_2 \) with increasing values of \( Q^2 \).

The transverse densities \( \rho_{ch,2}(b) \) are plotted with their error bands in Fig. 7 and Fig. 8. The errors are very small except for values of \( b \) less than about 0.1 fm. The results in this figure are the central numerical findings of this paper. The transverse densities \( \rho_{ch,2}(b) \) are broader than that of \( \rho_{ch} \) as previously observed.
FIG. 8: (Color online) $\rho_2$, with error bands

FIG. 9: (Color online) The true magnetization density $\rho_m$. The uncertainties are numerically negligible.

vanish at $b = R_2$. Then the FRA gives the result:

$$\rho_m = \frac{1}{\pi R_2^2} \sum_{n=1}^{\infty} J_{-2}(Q_1,n) b Q_2^2(n) F_2(Q_1,n) J_1(Q_1,n),$$

(35)

Once again we include the effects of the experimental error and the incompleteness error. This latter error is larger in this case than for $\rho_2$ because of the explicit factor of $X_{1,n}$. The result for $\rho_m$ and its error bands are plotted in Fig. 9. This quantity has a broader spatial extent than $\rho_2$, possibly resulting from the importance of the pion cloud in causing the anomalous magnetic moment. The uncertainties on this quantity are greater than for the other densities. Future measurements extending knowledge of $F_2$ to higher values of $Q^2$ would reduce these higher uncertainties.

VI. SUMMARY

This paper is concerned with obtaining a general method to determine information about densities in the transverse plane. The use of Bessel series expansion, augmented by the finite radius approximation (FRA) of Eq. (2), Eq. (3), Eq. (19) and Eq. (20) allows us to determine the effects of experimental uncertainties and also allows us to estimate the effects of the incompleteness error caused by a lack of measurements at large values of $Q^2$. The method can be applied to the extraction of any spatial quantity. One example, related to orbital angular momentum, is shown in Eq. (19) and Eq. (20).

The method is applied here to analyze electromagnetic form factors. We can see from Fig. 7 and Fig. 8 that the errors associated with the transverse charge density of Eq. (31), defined by taking the matrix element of $\frac{1}{4} \int d^3r \mathbf{b} \times \mathbf{j}$ in a transversely polarized state, allows an expansion in basis functions that explicitly

Note that the realistic transverse densities differ substantially from the dipole result of Eq. (24), shown in Fig. 2.

C. Extraction of $\rho_m(b)$

We now turn to the true transverse anomalous magnetic density of Eq. (31), defined by taking the matrix element of $\frac{1}{4} \int d^3r \mathbf{b} \times \mathbf{j}$ in a transversely polarized state. This Fourier transform involves $J_1(Qb)$ and therefore the FRA corresponds to that of Eq. (19) and Eq. (20), with $\lambda = 1$. Using this expansion, instead of simply taking the derivative of $\rho_2$, allows an expansion in basis functions that explicitly
density and the two-dimensional Fourier transform of $F_2$ are very small. The anomalous magnetization density $\rho_M$, Fig. 9, is also reasonably well determined, but future measurements extending our knowledge of $F_2$ to higher values of $Q^2$ would reduce the existing uncertainties.
