ABSTRACT

The weak-lensing science of the Large Synoptic Survey Telescope (LSST) project drives the need to carefully model and separate the instrumental artifacts from the intrinsic shear signal caused by gravitational lensing. The dominant source of the systematics for all ground-based telescopes is the spatial correlation of the point spread function (PSF) modulated by both atmospheric turbulence and optical aberrations in the telescope and camera system. In this paper, we present a full field-of-view simulation of the LSST images by modeling both the atmosphere and the system optics with the most current data for the telescope and camera specifications and the environment. To simulate the effects of atmospheric turbulence, we generated six-layer Kolmogorov/von Kármán phase screens with the parameters estimated from the on-site measurements. LSST will continuously sample the wavefront, correcting the optics alignment and focus. For the optics, we combined the ray-tracing tool ZEMAX and our simulated focal plane data to introduce realistic residual aberrations and focal plane height variations. Although this expected focal plane flatness deviation for LSST is small compared with that of other existing cameras, the fast f-ratio of the LSST optics makes this focal plane flatness variation and the resulting PSF discontinuities across the CCD boundaries significant challenges in our removal of the PSF-induced systematics. We resolve this complication by performing principal-component-analysis (PCA) CCD-by-CCD, and interpolating the basis functions derived from the analysis using conventional polynomials. We demonstrate that this PSF correction scheme reduces the residual PSF ellipticity correlation below \(10^{-7}\) over the cosmologically interesting (dark matter dominated) scale \(10^{-3}\). From a null test using Hubble Space Telescope (HST) Ultra Deep Field (UDF) galaxy images without input shear, we verify that the amplitude of the galaxy ellipticity correlation function, after the PSF correction, is consistent with the shot noise set by the finite number of objects. We conclude that the current optical design and specification for the accuracy in the focal plane assembly are sufficient to enable the control of the PSF systematics required for weak-lensing science with LSST.

1. INTRODUCTION

The Large Synoptic Survey Telescope (LSST) has been designed to provide a deep six-band (0.3-1.1 µm) astronomical imaging survey of more than 20,000 square degrees of the southern sky. Using active optics, the 8.4-meter aperture and 9.6 square degree field-of-view of the telescope will allow ~1000 visits to each patch of sky in ten years with a final depth reaching \(r \sim 27.5\) and a mean delivered PSF better than 0.7\(''\) (LSST Science Collaborations et al. 2009). The LSST project will deliver fully-calibrated, science quality images, catalogs, and derived data products to the US public with no proprietary period. We refer readers to LSST Science Book II (LSST Science Collaboration 2009) for extensive discussions on the science that the survey will enable.

Among the most critical science applications that the LSST will revolutionize is weak gravitational lensing. The key observable in weak gravitational lensing is the shape of distant galaxies weakly distorted by foreground masses. Because each galaxy is sheared only by a small amount, the lensing signal must be extracted from an average over a population of galaxies. Consequently, the total number of resolved galaxies at the usable surface brightness limit is one useful measure to quantify the effectiveness of an astronomical survey for weak-lensing science. Another important factor is the number density of usable galaxies (shear noise weighted effective number), which determines the lower limit of the angular scale that lensing can probe. The LSST project is designed to maximize the scientific return balancing both the total number (area) and the number density within the ten-year nominal mission period. A sky coverage of approximately 20,000 square degrees is required to keep the sample variance below the statistical limit, and the high-resolution (< 0.7\(''\) median delivered seeing), deep imaging (\(r \sim 27.5\)), providing > 40 high S/N galaxies per square arcmin enabling a reliable probe of matter structure on galaxy cluster scales. Residual uncorrected PSF shape variation requirements are summarized in the Science Requirement Documents: [http://www.lsst.org/files/LSST/Sci/SciReq/SciReq.pdf](http://www.lsst.org/files/LSST/Sci/SciReq/SciReq.pdf). These performance requirements determine the desired level of accuracy in point spread function (PSF) correction. The effect of the PSF on the galaxy shape measurement cannot be overemphasized. Anisotropic PSFs mimic gravitational lensing signal, generating a coherent alignment of galaxy shapes. Even without this anisotropy, PSFs circularize shapes of barely resolved galaxies and dilute the intrinsic lensing signal.
of the atmospheric turbulence is described in [3]. In Section [4] we discuss the focal plane design of LSST and the resulting behavior of the PSF. [5] presents our algorithm to measure and reconstruct the PSFs. In [6] we describe our simulation. Finally, the detailed comparison between the observed and modeled PSFs is presented in [7] before the conclusion in [8].

2. LSST ENVIRONMENT AND OPTICS

Figure [1] shows the optical design of the LSST, which is a modified Paul-Baker three-mirror system. The active optics telescope consists of an 8.4 m f/1.18 concave primary, a 3.4 m f/1.0 convex secondary, and 5.2 m f/0.83 concave tertiary mirrors. The final focal ratio f/1.23 (foveal length of 10.3 m) gives a plate scale 0.0197′′/μm over the 64 cm diameter focal plane (3.5° × 3.5°). The 27% obscuration yields a total effective light collecting area of 35 m², which corresponds to an effective 6.7 m diameter clear circular aperture. Current wide field telescopes were not designed for the stringent PSF demands of LSST weak lensing goals.

This optical design provides a wide field of view while a maintaining uniform image quality across the field (Seppala 2002). The remarkably small variation of the PSF size over the field is illustrated in Figure [2], where the diffraction-limited PSF images are generated with Zemax at the nominal flat focal plane. The peak-to-valley 80% encircled energy radius is within ~7% of the mean value from the center to ~1.4′′ for simulated I filter point sources. The maximum deviation (~17%) is seen at the edge of the field (1.75′′). The image brightness is stable across the field, providing a nearly uniform illumination within a radius of 1.2′′ and about 10% decrease at the edge (Seppala 2002; LSST Science Collaborations 2010). Finally, the LSST field distortion is remarkably small: less than 0.1% over the full field.

LSST will have continuous correction of its optics, using curvature wavefront sensing. Four special purpose rafts, mounted at the corners of the science array, contain wavefront sensors and guide sensors (right panel of Figure [1]). Wavefront measurements are accomplished using curvature sensing, in which the spatial intensity distribution of de-focused stars is measured at equal distances on either side of focus. Each curvature sensor is composed of two CCD detectors, with one positioned slightly above the focal plane, the other positioned slightly below the focal plane. The CCD technology for the curvature sensors is identical to that used for the science detectors in the focal plane, except that the curvature sensor detectors are half-size so they can be mounted as an in-out defocus pair. Detailed analyses (Mannel et al. 2010) have verified that this configuration can reconstruct the wavefront within the £ 0.2μm accuracy. These four corner rafts also hold two guide sensors each. The guide sensors monitor the locations of bright stars at a frequency of ~10 Hz to provide feedback for a loop that controls and maintains precision tracking of the telescope during an exposure.

The fast focal ratio and the rapid pointing changes make any hardware-based atmospheric dispersion correction technically difficult. Consequently, the effect of the atmospheric dispersion sets the maximum angle away from the zenith. We estimate the atmospheric differential refraction for the six proposed filters (u, g, r, i, z, and
Y) using the models summarized in Filippenko (1982). Figure 3 displays the results for the input parameters of $f = 8 \text{ mm Hg}$ (water vapor pressure), $T = 5^\circ \text{C}$ (atmospheric temperature), and $P = 520 \text{ mm Hg}$ (atmospheric pressure), which are the approximate average conditions at Cerro Pachón (Claver et al. 2004). Because the weak-lensing shape measurements will be carried out in $r$ and $i$ band images, it is critical for the $r$ and $i$ band imaging to provide the excellent seeing while still covering the required sky area of 20,000 square degrees. From Cerro Pachón, the required 20,000 square degrees of survey area are viewable above a zenith angle of 45 degrees. At this 45° limit, the corresponding dispersion in the $r$ and $i$ bands is less than $\sim 0.3'$, which elongates the PSF in the zenith angle direction by $\sim 9\%$ and gives a coherent PSF ellipticity of $\lesssim 0.04$ for $\sim 0.7''$ seeing. This amount of ellipticity by atmospheric dispersion is small and comparable to the values induced by the optical aberrations (after atmospheric turbulence). Therefore, we conclude that the LSST design does not require atmospheric dispersion corrector (ADC).

3. IMPLEMENTATION OF ATMOSPHERIC TURBULENCE

After the optics and camera are corrected by the wavefront sensing, the largest residuals are due to the atmosphere and the focal plane non-flatness. The simulation of the atmospherically distorted wavefront is the first step for the generation of the realistic PSF of LSST. A typical short exposure image of a star through atmospheric turbulence can be viewed as a superposition of a number of speckles. The spatial extent of each speckle is roughly determined by the diffraction limit of the instrument whereas the relative centroid shift between these speckles reflects the severity of the turbulence mainly depending on the amplitude of the low frequencies. To mimic these effects numerically, we follow the well-known classical approach which regards the atmosphere as consisting of multiple moving layers each with independent phase screen and velocity. Although a single phase screen has been shown to provide many characteristics of the real environments qualitatively, the wind speed must be unrealistically high $\sim 100 \text{ km s}^{-1}$ in order to correctly represent the time scale of the observed speckle changes. In principle, the turbulence affects both the magnitude and phase of the wavefront. However, because the phase distortion has a much larger effect for non-saturated scintillation (Fried 1994), in this paper we only consider the phase effect on the PSF behavior.

The power spectrum of the phase screen is usually described by the Kolmogorov/von Kármán model (Kolmogorov 1941; von Kármán 1930; Sasiela 1994):

$$
\Psi(\nu) = 0.023 r_0^{-5/3} \left( \frac{\nu^2 + 1}{L_0^2} \right)^{-11/6},
$$

where $\nu$, $r_0$, and $L_0$ are the two-dimensional frequency, the Fried parameter, and the outer scale, respectively. The outer scale $L_0$ is infinite for Kolmogorov screens. However, for a large telescope this approximation becomes invalid, leading to an over-prediction of the PSF size (e.g., Tokovinin & Travouillon 2006). We set $L_0$ to 25 m, which is close to the average value at Cerro Pachón determined by Ziad et al. (2000) from the measurement of the angle-of-arrival fluctuations.

The realization of the Kolmogorov/von Karman phase screen in the spatial domain is obtained by taking the inverse Fast Fourier Transform (FFT) of $\psi(\nu)$, whose modulus is given by $L/\Psi(\nu)$; $L$ refers to the physical length of the screen and the phase of $\psi(\nu)$ is random. For the two-dimensional array, where $i$ and $j$ are the indexes in the spatial domain, and $k$ and $l$ are the indexes in the frequency domain, $\psi(i, j)$ (the phase value at $i$ and $j$) is given by (e.g., Carlibet & Riccardi 2010)

$$
\psi(i, j) = \sqrt{2}\sqrt{0.023} \left( \frac{L}{r_0} \right)^{5/6} \times
$$

$$
\text{FFT}^{-1}_{R/L} \left[ \left( k^2 + l^2 + \left( \frac{L}{L_0} \right)^2 \right)^{-11/12} e^{i(\phi(l,j)1)} \right]
$$

In equation 2 $\text{FFT}^{-1}_{R/L}$ means that either real or imaginary part of the inverse FFT result is used (thus the additional factor $\sqrt{2}$ is present). $\phi(k,l)$ is the uniformly distributed random number in the range $-\pi \leq \phi < \pi$. Because we used FFT, one obvious drawback of the phase screen generated in this way is the lack of frequencies lower than the value set by the physical dimension of the array (i.e., $1/L_0$). Lane et al. (1992) suggest a compensation of this artifact by adding subharmonics to the result. However, this problem is not relevant in the current study because the simulation of LSST requires a large ($\gtrsim 1 \text{ km}$) phase screen to account for the large field of view.

For the realization of the specific environment for LSST, we adopt the results of Ellerbroek (2002), who provides the parameters of the atmospheric turbulence profile based on the measurements at Cerro Pachón, Chile, the site of the current Gemini-South telescope and also the future LSST observatory. The atmospheric profile consists of six layers at altitudes of 0, 2.58, 5.16, 7.73, 12.89, and 15.46 km as shown in Figure 3 with relative weights of 0.652, 0.172, 0.055, 0.025, 0.074, and 0.022, respectively (Ellerbroek 2002). The Fried parameter ($r_0$) is set to 0.16 m, which is reported to be an approximate median condition at the location by Ellerbroek (2002); for a large telescope with a diameter $D >> r_0$ short-exposure seeing is inversely proportional to $r_0$. Each layer is allowed to move independently at a constant velocity during the integration. The maximum wind velocity at the highest altitude is kept under $\sim 20 \text{ m s}^{-1}$, which determines the minimum time step 0.005 s (corresponding to $\sim 0.5$ pixel shift) to satisfy Nyquist sampling rate. We choose the dimension of our resulting phase screen array to be sufficiently large ($6 \times 8192 \times 8192$ or $6 \times 1.3\text{km} \times 1.3\text{km}$) in order to keep the moving phase screens covering the telescope field of view during the 15 s integration time.

The weighted average $\psi(x, y)$ of the six phase screens at a given moment can be converted to a snapshot of the telescope PSF in the absence of the optical aberration via the following equations:

$$
p(x, y) = A(x, y) e^{i2\pi \psi(x, y)/\lambda}
$$

$$
PSF = |\text{FFT}(p)|^2,
$$

Lane et al. (1992) suggest a compensation of this artifact by adding subharmonics to the result. However, this problem is not relevant in the current study because the simulation of LSST requires a large ($\gtrsim 1 \text{ km}$) phase screen to account for the large field of view.

For the realization of the specific environment for LSST, we adopt the results of Ellerbroek (2002), who provides the parameters of the atmospheric turbulence profile based on the measurements at Cerro Pachón, Chile, the site of the current Gemini-South telescope and also the future LSST observatory. The atmospheric profile consists of six layers at altitudes of 0, 2.58, 5.16, 7.73, 12.89, and 15.46 km as shown in Figure 3 with relative weights of 0.652, 0.172, 0.055, 0.025, 0.074, and 0.022, respectively (Ellerbroek 2002). The Fried parameter ($r_0$) is set to 0.16 m, which is reported to be an approximate median condition at the location by Ellerbroek (2002); for a large telescope with a diameter $D >> r_0$ short-exposure seeing is inversely proportional to $r_0$. Each layer is allowed to move independently at a constant velocity during the integration. The maximum wind velocity at the highest altitude is kept under $\sim 20 \text{ m s}^{-1}$, which determines the minimum time step 0.005 s (corresponding to $\sim 0.5$ pixel shift) to satisfy Nyquist sampling rate. We choose the dimension of our resulting phase screen array to be sufficiently large ($6 \times 8192 \times 8192$ or $6 \times 1.3\text{km} \times 1.3\text{km}$) in order to keep the moving phase screens covering the telescope field of view during the 15 s integration time.

The weighted average $\psi(x, y)$ of the six phase screens at a given moment can be converted to a snapshot of the telescope PSF in the absence of the optical aberration via the following equations:

$$
p(x, y) = A(x, y) e^{i2\pi \psi(x, y)/\lambda}
$$

$$
PSF = |\text{FFT}(p)|^2,
$$

where $\Psi(\nu) = 0.023 r_0^{-5/3} \left( \frac{\nu^2 + 1}{L_0^2} \right)^{-11/6},$
In equation $\xi$, $A(x, y)$ is the telescope pupil function (a mask showing the obscuration) and the phase difference $\psi(x, y)$ has the dimension of length. The pixel scale of the PSF array given by equation $\xi$ is simply $F \lambda / 2$, where $F$ is the f-ratio. Figure 4 displays the examples of the LSST PSFs generated in this way at different integration times. The PSF at $t = 0$ shows the typical instantaneous speckle. In this figure we do not include either the optical aberration or the charge diffusion by CCDs, the effects of which we however later add to generate the simulated LSST images. As the exposure time increases, more speckles are stacked together, which makes the resulting PSF rounder and the irregular features present in the individual speckles more smeared (de Vries et al. 2007).

A quantitative study on the impact of the atmospheric turbulence on the ellipticity and its spatial correlation is needed to support the validity of our simulation hereafter. As is discussed in [4], we model LSST PSF variation CCD-by-CCD with polynomials. If the anisotropic power from the atmosphere within 15 sec exposure turns out to be too strong and changes on a very small scale, any conventional interpolation scheme with the finite number of stars will over-smooth the inherent PSF variation.

We define the ellipticity of PSF as $(a-b)/(a+b)$, where $a$ and $b$ are the semi-major and -minor axes of the PSFs, respectively. In general, the PSF isophotes change with radius. Thus, the measurement somewhat depends on the weighting scheme. We measure the ellipticity of the PSF using the following quadrupole moments:

$$Q_{ij} = \frac{\int d^2 \theta W(\theta) I(\theta)(\psi_{i} - \psi_{j}) \psi_{i}(\psi_{j} - \psi_{j})}{\int d^2 \theta W(\theta) I(\theta)},$$

where $I(\theta)$ is the pixel intensity at $\theta$, $\psi_{ij}(\theta)$ is the center of the star, and $W(\theta)$ is the optimal weight function required to suppress the noise in the outskirts. For the diffraction-limited PSF of LSST (Figure 5), we choose a Gaussian with a FWHM of $\sim 0.3''$ for $W(\theta)$ whereas for the turbulence-limited PSF the FWHM of the Gaussian weight function used is $\sim 0.7''$. The quadrupole moments are converted to the ellipticity $\epsilon$ via:

$$\epsilon = \epsilon = \epsilon_x + \epsilon_y + 2Q_{11} - 2Q_{22} + 2Q_{12} - 2Q_{12},$$

where the product $\epsilon(r') \epsilon(r'' + r)$ is performed for each pair separated by $r$, and the $\epsilon_i$ and $\epsilon_x$ are the tangential and the $45^\circ$ components, respectively, with respect to the line connecting the pair. The amplitude of the correlation function decreases with exposure time. From the comparison with the contribution due to the telescope and camera aberration (see §4), we conclude that the small scale anisotropic power for the delivered PSF is not dominated by the atmospheric turbulence. These results have been validated with a series of 15 sec exposures of the globular cluster NGC2419 on the Subaru telescope.

4. LSST Focal Plane and Impacts on PSF

The 64 cm diameter focal plane of LSST will be tiled with 189 4k×4k CCDs. As-built heights might vary up to $\sim 10$ microns (peak-to-peak) in a complicated way relative to the nominal flat surface. Although this flatness deviation is small compared with other cameras in existing facilities, the small $f$-ratio of the instrument makes this focal plane flatness variation play a critical role in aberration-induced PSF behavior (depth of focus $\propto f$-ratio). In Table 1 we summarize the current specification of the focal plane error budget originally issued to vendors, as well as the values used for the current simulation. The CCD flatness technology and testing is reviewed in Takacs et al. (2006) and Radeka et al. (2009). The focal plane errors that we assume for the simulations in this paper are larger than the current expectation so that the results presented here are conservative. Several vendors are now exceeding these flatness specifications. A realization of the LSST focal plane based on these error distributions is displayed in Figure 7. The resulting behavior of the PSF ellipticity is illustrated in Figure 8. These PSFs are obtained by evaluating optical path difference functions across the focal plane in the absence of atmospheric turbulence using the ZEMAX software; see also Jarvis, Schechter, & Jain (2008) for the discussion on the impact of the telescope focus on the PSF ellipticity.

Several features are noteworthy in Figure 8. First, the aberration-induced ellipticity is large. Most of the large sticks in the plot exceed $\sim 10\%$ ellipticity, approaching nearly $30\%$ at the field edges. Because the maximum deviation in this realization is small ($\sim 10 \mu m$), these large values of ellipticity remind us that the focal error tolerance of LSST is indeed narrow; however, we note that in the central region ($\lesssim 1^\circ$) the sensitivity of PSF elongation to height error is somewhat mitigated. Second, sharp discontinuities of PSF ellipticity are present where the CCD heights also vary abruptly. Third, although it may be a bit difficult to recognize this feature in Figure 8 a small-scale variation is observed even within a CCD mainly due to the tilt and potato chip effects.

The presence of these smooth, small-scale variation and discontinuous changes across CCD gaps are the most challenging aspects of the PSF description and modeling for LSST. Any attempt to use a single set of polynomials to characterize the PSF behavior across the entire focal plane fails because the small-scale variation re-
quires impractical, high-order terms in the polynomials, and in addition no interpolation scheme can satisfactorily reproduce the sharp discontinuities across the CCD borders. This is the reason that in the current paper we perform interpolation CCD-by-CCD to model LSST PSFs. Considering the 1-2 cycles of the potato chip effect within a CCD, we estimate that 3-4 order polynomials suffice. The remaining question is what features of PSF are interpolated. A simple description of the two components of the PSF ellipticity has been used in the early weak-lensing analysis (e.g., Valdes, Jarvis, & Tyson 1983; Kaiser, Squires, & Broadhurst 1995). However, certainly ellipticity alone does not fully characterize a PSF. One obvious missing piece of information is the size of the PSF. One can imagine that a 10% ellipticity PSF with FWHM=1″ more strongly affects the shape of galaxies than a PSF with the same ellipticity but with FWHM=0.5″. Many authors (e.g., Hoekstra et al 1998, Kaiser 2000; Rhodes, Refregier, & Groth 2001) suggested modifications to this earlier method (Kaiser, Squires, & Broadhurst 1995) for the treatment of the PSF size. Nevertheless, this increased sophistication (i.e., ellipticity with size) is not still sufficient to obtain the accuracy that the LSST weak-lensing science requires.

On the other extreme, one might consider interpolating pixel values of observed PSFs. The result of this type of PSF interpolation is the actual image of the PSF, which in principle contains the most complete information at any point in the focal plane. However, this scheme faces severe practical challenges in the implementation because 1) except for the pixels near the core, individual PSF images are noisy, and 2) the number of needed polynomials become prohibitively large as one enlarges the dimension of the PSF. Therefore, one might imagine that a new PSF description scheme should provide sufficient details with both an efficient noise filtering method and a compact set of polynomials. A natural choice is the description of the PSFs using some basis functions, preferably an orthogonal set to avoid degeneracy and thus improve compactness. Bernstein & Jarvis (2002) and Refregier (2003) suggest the use of eigenfunctions of two-dimensional PSF images as shapelets) for this purpose. Although the shapelet approach is shown to work in many applications, Jae et al. (2007) demonstrate that the basis functions are still suboptimal, truncating the PSF profile much earlier than desired. Consequently, Jae et al. (2007) proposed to derive the basis functions from the data themselves via principal component analysis (PCA).

Lupton et al. (2001) first mentioned the use of PCA for the modeling of the Sloan Digital Sky Survey (SDSS). Although the details of the implementation were not given, the method is similar to that of Jae et al. (2007) in that PCA is employed to derive the optimal basis functions from the data themselves. On the other hand, the use of PCA by Jarvis & Jain (2004) and Schrabback et al. (2010) for the description of the PSF variation is somewhat different from the method of Jae et al. (2007) because they use PCA to characterize the pattern of the variation (e.g., coefficients or ellipticity components), not to capture the pixelated PSF features.

Our PCA approach has been so far applied to weak-lensing studies only with Hubble Space Telescope images (e.g., Jae et al. 2009). In the current investigation, we adopt this PCA scheme to characterize/model the LSST PSFs. As our PCA algorithm is independent of the specification of the instrument, the implementation in Jae et al. (2007) can be used with little modifications. The technical details of the PCA method will be reviewed in the following section.

5. PRINCIPAL COMPONENT ANALYSIS

PCA is the mathematical procedure for analyzing multivariate data by finding and utilizing a new orthogonal coordinate system, which substantially reduces the number of axes relative to the original number of variables for the characterization of the data. Inevitably, the procedure involves information loss. However, in the typical data set where the noise is significant, this reduction of the information in fact works as filtering, enabling a compact description of the data without significantly harming its integrity. In the current paper, we explain the procedure using our specific data set, i.e., series of noisy two-dimensional PSF images. A similar account can be also found in Jae et al. (2007).

Let us assume that we have \( N \) observed stars in a \( 4k \times 4k \) CCD image with random positions and brightness. The two-dimensional array of each PSF image can be rearranged to form a one-dimensional vector. How we exactly scramble the pixels of the PSF image is not important in the subsequent analysis as long as we have the ability to re-order the pixels to recover the original two-dimensional image. However, it is critical that each PSF image is carefully background-subtracted and normalized prior to the rearrangement. Then, the \( N \) one-dimensional vectors are stacked to comprise a matrix. If each PSF image contains \( M \) pixels, the result is a \( N \times M \) matrix. The next step is to evaluate mean values along the columns, and subtract this \( 1 \times M \) mean vector from each row of the matrix. In practice, each row of the \( N \times M \) matrix contains star images contaminated by neighboring objects, cosmic rays, bad pixels, etc. Therefore, the mean values are preferably evaluated iteratively with some outlier rejection. Also, the rejected pixel values in the \( N \times M \) matrix should be replaced with the mean values. Because we need this mean vector to reconstruct the PSF later, this mean vector (or mean PSF rearranged in one-dimension) must be saved.

Now, we are ready to find a set of \( P (<< MIN(N, M)) \) orthogonal vectors that compactly describe the \( N \times M \) matrix. One way to derive such orthogonal vectors is Singular Value Decomposition (SVD; Press et al. 1992). If we call the \( N \times M \) matrix \( \mathbf{S} \), the matrix \( \mathbf{S} \) can be decomposed in the following way:

\[
\mathbf{S} = \mathbf{U} \mathbf{W} \mathbf{V}^T,
\]

where \( \mathbf{U} \) is an \( N \times M \) column-orthogonal matrix, \( \mathbf{W} \) is an \( M \times M \) diagonal matrix, and \( \mathbf{V} \) is an \( M \times M \) orthogonal matrix. The diagonal elements of \( \mathbf{W} \) are called singular values.

Therefore, the matrix component \( S_{ij} \) can be expressed as

\[
S_{ij} = \sum_{k=1}^{M} w_k U_{ik} V_{jk},
\]

which implies that, if some singular values \( w_k \) are relatively small, we can substitute zeros for those \( w_k \)’s with-
out greatly compromising the numerical accuracy of the matrix evaluation. In other words, the reconstruction of $S$ is possible with fewer columns in both $U$ and $V$, and thus the procedure provides a substantial compression of the information in the original matrix $S$, where photon and detector noise is a significant part. The remaining columns (principal components) of $V$ form an orthogonal basis, and in this analysis we refer to these eigenfunctions as eigenPSFs. We display examples of these eigenPSFs in Figure 1. These eigenPSFs in this figure are obtained from the PCA of 4000 simulated stars on the entire focal plane in the absence of telescope aberration and CCD height fluctuation, but in the presence of the atmospheric turbulence. The eigenPSFs are ranked according to the size of their eigenvalues with $n = 0$ representing the largest. Note the remarkable resemblance of the first several eigenPSFs to the basis functions in the shapelet approach. However, also note the asymmetry of the eigenPSFs due to the characteristic pattern of the specific data set. For increasing $n$, more high-frequency features are evident. Above a certain limit $n = n_c$, the resulting eigenPSFs start to reflect the noise features without contributing to the PSF reconstruction. Consequently, we need only a truncated set of eigenPSFs to describe the behavior of the PSF.

This minimal number of eigenPSFs can be determined by examining the eigenvalues of each eigenPSF. In general, there is a conspicuous “kink” at a certain $n = n_c$, beyond which the decrease of the eigenvalue suddenly slows down (e.g., Figure 5 of Jee et al. 2007). We find that $\sim 20$ eigenPSFs are sufficient to describe the details for both space- and ground-based telescope PSFs.

After the eigenPSFs are obtained, the $k^{th}$ star used for the derivation is decomposed as

$$C_k(i, j) = \sum_{n=0}^{n_{max}} a_{kn} P_n(i, j) + T(i, j), \quad (10)$$

where $C_k(i, j)$ is the normalized pixel value of the $k^{th}$ star at the pixel coordinate $(i, j)$, $P_n$ is the $n^{th}$ eigenPSF, $a_{kn}$ is the projection of the $k^{th}$ star in $P_n$, and $T$ is the mean PSF. Because $P_n$’s are orthogonal to one another, one does not need to determine $a_{kn}$ through some $\chi^2$ minimization here.

Now the PSF at any arbitrary location can be evaluated through polynomial interpolation of $a_{kn}$’s:

$$a_n = \sum_{l, m=0}^{l+m \leq N} d_{nlm} x^l y^m, \quad (11)$$

where $x$ and $y$ are the coordinate of the position, at which one wants to know the PSF, $d_{nlm}$ is the coefficient of the term $x^l y^m$ for the $n^{th}$ eigenPSF, and $N$ is the maximum order of the polynomial. It is important to determine $d_{nlm}$ without the application of the S/N weight of the star because we are interested in the spatial variation of the PSF.

6. SIMULATION OF LSST IMAGES AND PSF RECONSTRUCTION

For the robust simulation of the weak-lensing shear extraction using LSST, it is crucial that the simulated image contains astronomical objects with realistic photometric, morphological, and statistical properties, as well as the instrumental artifacts resulting from the known characteristics of the telescope, camera, and the environment. Specifically, the requirements include our ability to correctly represent:

1. the number density and luminosity function of unsaturated high S/N Galactic stars,
2. the number density, luminosity function, size, and morphology of galaxies,
3. position-dependent PSF variations,
4. geometric-dependent PSF variations, and
5. atmospheric turbulence and dispersion.

The first requirement is needed because the number of available high S/N stars determines how well we can measure the behavior of the PSFs. In particular, we need to investigate if the nominal 15 s exposure image provides sufficient number of usable stars within a CCD so as to correctly sample the position-dependent PSF variation.

The next point relates to the issue of both statistical and systematic errors of the shear measurement from galaxy ellipticity. The number of usable galaxies for testing lensing analysis affects the statistical accuracy of the estimate of shear and our determination of mass. In addition, one important source of bias in many ellipticity measurement techniques is the under-fitting of galaxy shapes (i.e., the model galaxy profile assumed is different from the real profile). Since many $z \gtrsim 1$ galaxies are dominated by so-called faint blue galaxy (FBG) population incapable of being described by analytic functions, it is important that the image contain a realistic fraction of these irregular galaxies. The extremely high sensitivity of the LSST PSF to the focal plane errors makes the position-dependent PSF one of the most critical features to be simulated. We need to generate the realistic PSF and convolve the galaxy image with this position-dependent PSF in a time-efficient way.

Although expected to be very small, the geometric distortion by the telescope and atmosphere can correlate ellipticity of galaxies and mimic gravitational lensing signal similar to the way that uncorrected PSF can cause systematic alignment of galaxy ellipticity. It is essential to estimate the level of accuracy in rectifying the raw images and the effects on shear measurement.

The atmospheric turbulence and dispersion are dominant sources of time-dependent PSF variation. Unlike the telescope and camera optical aberration, the atmospheric turbulence is believed to circularize the PSF rather than to introduce significant anisotropy whereas the atmospheric dispersion obviously elongates the PSF in the direction of the zenith angle. It goes without saying that these atmospheric effects should be properly included in the simulation.

Our simulation of the LSST shear test is an on-going project, and the final goal is to carry out an end-to-end simulation from the realization of the LSST image from an input cosmology to the full recovery of the galaxy shear signal and the cosmological parameters. Hence, it is our ultimate aim to rely on the final simulator not only to implement the above requirements but also to address other non-shear measurement issues such as diffuse components, cosmic rays, hot/warm/bad pixels, etc.
This end-to-end simulation is being done by The LSST Simulations Team (Connolly et al. 2010).

Here, as a pilot study, we focus on generating realistic LSST PSFs and recovering these input PSFs from sparse distribution of the stars in the presence of background galaxies. Therefore, some simplifications are made where they do not significantly compromise the integrity of our simulation relevant to the focal plane flatness issue.

6.1. Generation of Input PSF Model

First, we generate the coordinates of the model stars that are densely distributed across the focal plane. Because we will evaluate the fiducial PSFs at these locations and interpolate the results to describe the PSF on every pixel, the density of these stars should be high enough to accommodate the expected small scale variation. We assigned about 800 stars to each CCD and verify that these 800 stars sample with ample resolution the spatial variation, which is dominantly modulated by potato-chip effects (1-2 cycles per CCD). Then, we evaluate the diffraction-limited PSF at the location of those stars using ZEMAX. Strictly speaking, in this step we save phase data rather than PSFs because the optical phase data should be later combined with the atmospheric phase screen to generate the final PSF. We use the simulated focal plane height fluctuation shown in Figure 4 in order to provide the focus value for each star. In the current investigation, our main interest is the ability to model/recover the PSF in the r band. Thus, we simulate the broadband effect by obtaining the data at five uniformly spaced wavelengths between 5450-7030 Å. Next, the atmospheric phase screen is evaluated at the location of each star. This atmospheric phase information is merged with the optical data to construct the next stage PSF. Finally, the result is further convolved twice to mimic the effects of the charge diffusion (∼ 0.4 pixel rms) within a CCD and the atmospheric dispersion (close to zenith).

We derive sets of eigenPSFs separately for each CCD. Alternatively, one can consider finding one set of eigenPSFs utilizing all PSFs on the focal plane. Although this latter scheme may reduce statistical errors, it appears that the resulting eigenPSFs are suboptimal, somewhat under-predicting the systematic pattern unique in each CCD. We choose to keep the most significant 20 eigenPSFs, which accounts for more than 99% of the total variance. Now each PSF is described by 20 coefficients each representing the amplitude in each eigenPSF direction. We fit 4th order polynomials to the coefficients of all stars to describe the PSF at any arbitrary location.

6.2. LSST Galaxy Image Generation

One ideal way to generate galaxy images for a given cosmology is to make a catalog using large numerical simulation results (e.g., Millennium Simulation, Springel et al. 2005) with ray-tracing technique, to assign proper spectral energy distribution (SED) and morphology to individual galaxies, and to convert the catalog to astronomical images. However, this full scale end-to-end simulation (Connolly et al. 2010) is beyond the scope of the current project, and here we instead utilize Hubble Space Telescope (HST) Ultra Deep Field (UDF) images to sample galaxies. The HST UDF (Beckwith et al. 2003) is a 412-orbit HST Cycle 12 program to image a single field with the Wide Field Camera (WFC) of the Advanced Camera for Surveys (ACS) in four filters: F435W, F606W, F775W, and F850LP. The total exposure time of the F775W image is ∼ 350 ks, and the 10 σ limiting magnitude is 29 ABmag. The depth of the UDF image is sufficient for the generation of the galaxies that will be imaged by LSST, which reaches r ∼ 27.5 mag (∼ 5σ) in the final depth. Hence, virtually, the UDF data provide noiseless, seeing-free galaxies (the size of the ACS PSF is less than that of one LSST pixel) for a 15 s exposure. As the field of view of the ACS is ∼ 3’ × 3’, even smaller than the area covered by one LSST ∼ 14’ × 14’ CCD, it is inevitable that the same UDF galaxies must appear multiple times across the focal plane. However, this is not likely to compromise the accuracy of the current weak-lensing simulation, where we do not attempt to recover any input cosmology.

The high level science product of the UDF is publicly available and we use the F775W image to sample galaxies. Objects were detected via SExtractor (Bertin & Arnouts 1996) by looking for 8 continuous pixels above the sky rms. Postage stamp images were created by cropping a square region centered on the object with the side five times the semimajor axis of the SExtractor estimate. We used the segmentation map to check if any pixels belonging to other objects were present in the square. If so, we filled these pixels with the randomized background whose statistics were tuned to match the SExtractor estimate. Any objects whose half-light radii were less than the upper limit of the HST PSF value were discarded.

The next procedure is to plant these postage stamp UDF galaxy images onto each 4k × 4k CCD image. We looped over the list of the postage stamp images sequentially but randomizing the location and the orientation. The loop ended when the desired number density was reached. A large fraction of the pixels were the result of the superposition of many different postage stamp images. Thus, it is apparent that the noise level of these pixels vary slightly depending on the number of overlaps. However, because we later introduce much larger additional noise to simulate the 15 s exposure data, this noise variation is negligible.

A stellar count study based on the SDSS catalog (Jurić et al. 2008) shows that a single 4k × 4k CCD image (∼ 14″ × 14″) in 15 s exposure at the Galactic north pole is expected to contain at least ∼ 140 high S/N stars (≥ 30σ), which can be used to model the PSF. However, in the current simulation we conservatively distributed 40 point sources per CCD in such a way that the S/N of those stars remain above 30 in 15 s exposure, assuming the following differential star count: \( \phi(m) \propto 10^{0.2m-3} \); we find that PSF reconstruction with different magnitude distribution does not impact the quality of the PSF reconstruction as long as all the stars used have S/N > 30.

Prior to the noise generation, the “perfect” 4k × 4k image must be convolved with the position-dependent PSF of the CCD. Because our PSF is represented by 20 coefficients and 20 basis functions, it provides us with a convenient way to implement the spatially varying convolution. To begin with, we convolve a 4k × 4k seeing-free astronomical image with 20 eigenPSFs via FFT. The re-

\[ \text{http://archive.stsci.edu/prepds/udf/} \]
sults of this operation are 20 $4k \times 4k$ images. Then, using the resulting 4th order polynomial fitting we generate another 20 $4k \times 4k$ images with each pixel containing the coefficient (amplitude) of the eigenPSF. Next, we multiply each eigenPSF-convolved image with the matching coefficient image, obtaining 20 new $4k \times 4k$ images. These 20 images are simply stacked together to produce one $4k \times 4k$ image. This image is not yet the final image that we desire to generate because the 20 eigenPSFs are derived from the mean-subtracted PSFs. Therefore, we need to convolve the seeing-free $4k \times 4k$ image with the mean PSF, and add the result to the former $4k \times 4k$ image to yield the final $4k \times 4k$ LSST image. Figure 10 displays a $100'' \times 100''$ cutout from one of the 189 $4k \times 4k$ images. The noise-free (except for the existing low-level noise in the ACS UDF image) LSST-seeing-convolved image is shown in the left panel. This “ultra deep” image is about 2 mag deeper than the median depth LSST image (middle) after the completion of the nominal 10 year mission with 200 exposures per sky patch. The nominal 15 s LSST single exposure simulation is shown in the right panel.

7. SIMULATED IMAGE ANALYSIS AND RESULTS

7.1. PSF Reconstruction

The procedure to apply PCA to the simulated LSST image containing galaxies and stars is similar to the one discussed in the case of the input PSF modeling. The difference is that now we have far fewer stars, realistic noise, and neighboring objects. As a matter of course, this will provide the reconstructed PSF with fewer degrees of freedom in the description of the spatial variation. Hence, if the intrinsic PSF variation within a CCD is more complicated than what the reconstructed model can predict, the weak-lensing science with LSST will be substantially compromised. In this section, we present the detailed comparison between the reconstructed PSF and the input PSF in order to address this critical issue.

Astronomical objects in the simulated 189 $4k \times 4k$ images were detected with SExtractor. Stars were selected by utilizing half light radius versus magnitude relation as performed in typical lensing analysis. The stellar locus is well defined for bright stars. In addition, using ellipticity, comparison of half-light radius with FWHM measurement, and source extraction history (e.g., presence of close neighbor, edge clipping, etc.), the contamination becomes negligible in the current 10 sq. degree simulation. The cutout size is chosen to be $31\text{pixel} \times 31\text{pixel}$ ($6.2'' \times 6.2''$) after the star is sub-pixel shifted to place the centroid on a center of pixel. The ellipticity of the selected stars are displayed in Figure 11. We overlay the “whiskers” over the focal plane image that we use for the input PSF generation. The pattern of the PSF variation resembles the case displayed in Figure 8 where no atmospheric effect is included. However, the reduction of the magnitude is apparent due to the circularization effect of the atmospheric turbulence. We observe that no significant anisotropy is introduced by the moving phase screens. The PSF elongation in the zenith angle direction is very small here because we choose a telescope pointing to be close to the zenith.

We derive eigenPSFs for each CCD separately and use 3rd order polynomials to describe the spatial variation. For the visualization of how well the reconstructed model represents the observed pattern, we display the residual ellipticity distribution across the focal plane in Figure 12. The residual in Figure 12 is the difference in ellipticity $(e_+, e_-)$ of the observed (simulated) stars and the model PSF evaluated at the location of the stars. Consequently, any correct model should not only reduce the size of the “whiskers” in Figure 11 but also make the correlation of their size and the orientation decrease significantly. Visual comparison of Figure 12 with Figure 11 shows qualitatively that our interpolated PSF at the location of the stars closely mimics the pattern of the observed PSFs. One method to quantitatively examine the reduction of the whiskers is to compare the ellipticity component distribution in the two cases. In Figure 13 the blue dots represent the ellipticity components of the observed stars whereas the red dots indicate those of the residuals. Note that the residual ellipticity distribution is much more compact and is precisely centered on the origin $(e_+, e_-) = (0, 0)$.

Figure 14 displays the ellipticity correlation. The spatial correlation of the observed ellipticity (before PCA correction) has an amplitude of $3 \times 10^{-5}$. For a sanity check, we compared this amplitude with the values that we obtain from real observations, and found that they agree well. For example, the amplitude of the intrinsic PSF correlation before correction is $\sim 4 \times 10^{-5}$ and $\sim 3 \times 10^{-5}$ in the Deep Lens Survey (DLS; Wittman et al. 2002) field from the 4m Kitt Peak telescope and 8m Subaru telescope images, respectively; one should use caution when comparing these values to other published results because of different ellipticity definitions and weight functions.

Also displayed in Figure 14 is the ellipticity correlation function of the purely atmospheric PSF (Figure 6), which is generated by “turning off” optical aberrations. These PSFs are free from interpolation errors and thus help us to assess the amount of the atmospheric contribution to the PSF anisotropy. In particular, the comparison enables us to verify that 800 stars per CCD is sufficient to model the PSF pattern within a CCD. If the atmospheric PSF possessed a significant power on a small scale $r < 1'$, those 800 stars could not adequately sample the PSF variation.

Obviously, the amplitude $3 \times 10^{-5}$ of the ellipticity correlation for the observed PSF (blue) is higher than the expected cosmic shear signal for the ACDM universe at large angles. This implies that without PSF correction the galaxy ellipticity correlation will be dominated by the PSF systematics rather than by the intrinsic lensing signal. It is reassuring that the correlation function of the residual ellipticity components has an amplitude of $\sim 10^{-8}$, which is more than 3 orders of magnitude reduction in correlation and also more than 2 orders of magnitude below the anticipated cosmic shear lensing signal (see Rowe 2010 for the discussion and use of the residual ellipticity correlation in detail). We find similar improvement when we apply the PCA PSF corrections to the DLS data.

It is important to remember that the above PSF correlation is measured on a single 15 s exposure image. In fact, LSST will visit the same patch of the sky roughly 200 times in each filter used for weak-lensing with two 15
s exposures. Before each exposure the telescope optics is updated from the wavefront sensing system. The pupil rotation, sky rotation, and $x-y$ dithers will mix different systematic PSF patterns and reduce the intrinsic ellipticity of the PSFs in the final stack. In addition, this will also remove the spatial correlation that we saw within a single CCD even before we apply PSF corrections.

Although one can come up with an optimized operation scheme, which takes full advantage of hundreds of visits, we observe that even a simple random field rotation can dramatically reduce the intrinsic PSF ellipticity correlation. Figure 15 schematically displays this simple observing pattern and the resulting PSF ellipticity distribution. We illustrate an over-simplified observing scenario, where a same patch of the sky is visited 100 times with randomized roll angles.

In order to create the stack image out of these 100 frames, we arbitrarily choose one frame as a reference and rotate the rest of the frames for the alignment. Stacking rotated images are highly non-trivial in the presence of anisotropy in pixel boundaries, atmospheric dispersion, satellite trails, cosmic rays, detector response variation, internally scattered light/ghosts, etc. Numerous schemes exist for fractional pixel handing. We use bi-cubic interpolation (Press et al. 1992), which closely mimics the ideal sinc interpolation or its variations (e.g., Lanczos kernels), for both stacking images and constructing PSFs; the merits of using Lanczos kernels are discussed in the literature (e.g., Jee et al. 2007; Bertin 2010). The atmospheric dispersion is very small in the current simulation because we simulated pointings near the zenith. Thus, the dispersion correction is omitted in the current simulation. However, we think this atmospheric dispersion and other aforementioned real world problems must be handled with care because any small bias may appear as second-order systematics after analysing many billion single 15 s observations (upper left). The lower left panel shows the reconstructed PSF by first performing PCA on each exposure and then stacking all model PSFs after correct application of field rotation; the rotated PSFs are created by re-sampling with bi-cubic interpolation, which is identical to the procedure in the image stacking above. Stacking different PSF patterns reduces the correlation in observed PSF (Figure 16) However, it does not bring down the amplitude below $10^{-7}$ over the entire range of angular scales. This is because our toy model observing scheme without $x-y$ dithers does not mix different PSFs efficiently.

7.2. Null Test with Galaxies

The high-fidelity reconstruction of the observed PSF through PCA demonstrated in (7.1) hints at the prospect that the resulting galaxy shear measurement can be carried out with similarly small systematic errors. However, there remain several issues. First, anisotropic PSFs change the pixel noise properties also anisotropically, and thus even with the knowledge of the perfect PSF the resulting galaxy shape measurement can be still biased along the elongation of the PSFs. Related to this point is the centroid bias (e.g., Kaiser 2000; Bernstein & Jarvis 2002), which causes the object centroid to be more uncertain in the direction of the PSF elongation. Second, our comparison between the model and the observation is limited to the PSFs at the location of the stars. If the intrinsic spatial variation of the PSF has higher frequency than the order of the polynomial (3rd order here), it is possible that galaxy shape measurements would be carried out with suboptimal PSFs. Third, apart from PSF modeling, the difference in galaxy radial profile between assumption and reality can cause biases in shear extraction as suggested by Bernstein (2010). Fourth, it is not yet clear how to handle the pixelization effect optimally.

We use the single realization of the focal plane (shown in Figure 7) in the above multi-epoch simulation although we randomize the phase of the atmospheric turbulence screen for each epoch. It is important to realize that this simulation setup for the telescope and camera closely reflects the planned operation scheme of LSST. The LSST camera will maintain its fixed focal plane configuration throughout the mission, and the mirror deformation and alignment changes will be corrected with actuators to $\leq 0.2\mu m$ accuracy (Manuel et al. 2010). That is, the difference in aberration for different visits is small compared to the aberration introduced by the focal plane non-flatness. In principle, this small wavefront reconstruction error may slightly alter the resulting telescope aberration patterns exposure by exposure. However, the wavefront reconstruction error in different exposures are random, and stacking many exposures will reduce the correlation, circularizing the final PSFs to our advantage.

In Figure 15 the observed PSF ellipticity after stacking (upper right) is much smaller than what is seen in individual exposures.

\begin{equation}
\gamma^o - \gamma^t = m \gamma^t + c, \tag{12}
\end{equation}

where $m$ and $c$ are the calibration and anisotropic biases, respectively, and $\gamma^o$ and $\gamma^t$ are the observed and true shears, respectively. Despite the difficulties mentioned above, as a last resort the calibration bias or multiplicative factor $m$ can be determined through extensive weak-lensing science.
image simulations. We prefer a method which provides self-contained calibration factor and relies on the image simulation result only as a confirmation tool. Within the scope of this paper, we address the second issue, i.e., the removal of anisotropic bias, by performing “null” test on the simulated LSST images. In particular, we focus on how well a simple field rotation can remove this additive factor.

For the measurement of the galaxy ellipticity, we fit PSF-convolved elliptical Gaussians (e.g., Jee et al. 2009) to galaxies. As mentioned in the PSF on the final stack is constructed from the superposition of the 100 PSFs from all visits. We discard objects whose half-light radius is less than 1.2 times the median value of the stars or ellipticity measurement errors greater than 0.2. The resulting number of usable galaxies is \( \sim 40 \) per sq. arcmin for the depth at the completion of the nominal LSST survey, which meets the weak-lensing science requirement (LSST Science Collaborations et al. 2009). The exact value of the selection criteria should be determined in conjunction with the study of shear calibration, and thus will be the subject of our future publications.

As no shear is introduced, the galaxy correlation function should possess amplitudes consistent with the shot noise. One should remember that since the intrinsic ellipticity of individual galaxies are at least a factor of 10 larger than that of PSFs, the correlation function within a single LSST field will not approach the level of the residual PSF correlation function.

In Figure 17, we present this “null” test result with galaxy ellipticity for the 10 sq. degree field. If anisotropic PSF effects are corrected, the correlation amplitude should simply reflect the statistical galaxy shot noise as observed. As the number of exposures increases, the correlation amplitude goes down because the residual PSFs become more uncorrelated (systematic noise) and also the increased depth gives higher number of galaxies usable for shear measurements (statistical shot noise). The number density of galaxies with sufficiently high S/N for ellipticity measurement for a single, 10, and 100 exposures are 10, 24, and 42 galaxies per sq. arcmin, respectively. We find that the mean amplitudes of the galaxy ellipticity correlation functions are closely proportional to the inverse of these number densities (Figure 15). This tight relation implies that the level of the systematic error for the 100 exposure data set is much less than that of the statistical error (\( \lesssim 10^{-7} \)). The expected signal for a ΛCDM cosmology corresponds to a galaxy ellipticity correlation \( \sim 10^{-6} \) over this range of angular scale. The exact level of the systematic floor can be estimated only by extending the area of the simulation by a large amount. For the case that the amplitude of the PSF ellipticity correlation function \( \sim 10^{-8} \) happens to be the fundamental limit, we estimate the extrapolated correlation function for the 20,000 sq. degree area survey (cyan line in Figure 17).

8. CONCLUSIONS AND SUMMARY

We have investigated how the atmospheric turbulence and the telescope aberrations will impact the PSF of the active optics LSST in the context of weak lensing science. The atmospheric turbulence simulated by six moving Kolmogorov phase screens mainly contributes to the broadening of the diffraction-limited PSF (that would have been obtained in the absence of the atmosphere) without significantly inducing additional anisotropy. The FWHM \( \sim 0.7" \) of the simulated PSF nicely agrees with the mean value determined by the LSST seeing monitoring program at Cerro Pachón. The instrumental aberrations place potential challenges to precision weak-lensing analysis with LSST because of the fast f-ratio of the optics. Our simulation shows that the resulting shallow focal depth creates abrupt changes in PSF pattern across CCD borders. As the 3.5° × 3.5° focal plane will be tiled with 189 CCDs each having its own surface distortion (i.e., potato-chip effect), the PSF pattern on the entire focal plane is very complex.

However, we demonstrate that the complexity of the PSF pattern over the entire focal plane can be nicely described by interpolation with basis functions derived by PCA. In order to account for the discontinuity across the CCD borders with polynomials, the basis functions and the polynomial coefficients are determined separately for each CCD. This PSF recovery test is carried out with simulated LSST images containing realistic galaxies, as well as stars in the presence of photon noise and neighboring objects. The residual PSF ellipticity correlation function has amplitudes of \( 10^{-8} \) over the range, significantly lower than the amplitudes of the cosmic shear and the raw PSF ellipticity correlation.

It is critical to remember that in actual LSST operations the same patch of sky will be visited multiple times with different combinations of pupil rotation, sky rotation, and \( x-y \) dither. Hence, this will substantially reduce our burden in modeling the PSF for individual exposures because the mix of different PSF patterns will circularize the PSF in the stacked image and also decreases the spatial correlation. To illustrate how much the stacking procedure can improve the systematics, we simulate a toy case, where 100 visits are randomly rotated around the center of the field. The reduction in both ellipticity and correlation prior to any PSF modeling and correction is dramatic even in this simplistic scenario. The “null” test with galaxies in the stacked image indicates that the amplitude of the galaxy shear correlation is consistent with the level of the shot noise, indicating that the systematic error is not detectable within a single \( \sim 10 \) sq. degree field with 100 exposures.

The PSF anisotropy correction (additive factor in shear recovery) is one of the most poorly investigated effects, and the literature disagrees on the best approaches. Our current simulation shows that the anisotropic PSF effects can be sufficiently corrected with the current design of LSST. This improvement is enabled by both a new PCA algorithm and the large étendue and active optics of LSST capable of turning systematics into statistics. In a forthcoming paper, we will extend the current simulation with the addition of input galaxy shear and discuss the accuracy of the shear recovery with existing algorithms.

Fig. 1.— LSST optical design. The telescope design (left) is a modified Paul-Baker three mirror system, which produces a uniform image quality across a large field of view. The relative positions of the primary and the tertiary mirrors were adjusted during the design process so that their surfaces meet with no axial discontinuity at a cusp, allowing the Primary and the Tertiary to be fabricated from a single substrate. The 3.4-m convex secondary mirror has a 1.8 m inner opening, through which the LSST camera is inserted at the focal plane. The focal plane (right) is tiled with 189 4k × 4k CCDs. There are four wavefront sensors and eight guide sensors, located in the four corners of the CCD array. All optics and the camera are corrected with active optics wavefront curvature sensing. The red solid circle represents the 3.5° diameter field of view boundary.

Fig. 2.— Encircled energy of LSST PSF. Here we estimate the diffraction-limited encircled energy for $i$ filter. The left panel shows the encircled energy as a function of radius for the four locations on the focal plane. On the right panel the 80% encircled energy radius as a function of the focal plane location (distance from the principal axis) is plotted. The inset images display the snapshot of the PSFs at 0° (center), 0.5°, 1°, 1.2°, and 1.75° (edge). Note the remarkably small variation of the PSF size across the entire focal plane.
Fig. 3.— Simulated Atmospheric dispersion at the proposed LSST site. We used the dispersion models summarized in Filippenko (1992) assuming $f = 8$ mm Hg (water vapor pressure), $T = 5^\circ$C (atmospheric temperature), and $P = 520$ mm Hg (atmospheric pressure), which are the approximate average conditions at Cerro Pachón (Claver et al. 2004).

Fig. 4.— Six layers of Kolmogorov/von Karman phase screens used for the atmospheric turbulence model.
Fig. 5.— Example of time evolution of simulated LSST PSF due to atmospheric turbulence at the zenith. The displayed PSFs are for the monochromatic beam at $\lambda = 6000\,\text{Å}$. We do not include the optical aberration or the charge diffusion by CCDs in this simulation. As the exposure time increases, more speckles are stacked together, which makes the resulting PSF rounder and the surface brightness irregularities decrease. The FWHM at $t \sim 15\,\text{s}$ is $\sim 0.5\,\text{″}$. 
Fig. 6.— Impacts of turbulence on PSF. (a) PSF ellipticity (spatial) variation for the 15 s exposure within a 4k×4k CCD of LSST due to atmosphere. Because no optical aberration is introduced yet, this plot shows purely atmospheric contribution. A clear spatial correlation is visible on a scale of ∼1′ (∼300 pixels). However, the average magnitude is less than 1%, and thus the resulting anisotropy does not contribute significantly to the final PSF. (b) Ellipticity correlation for different exposure times. The amplitude of the correlation function decreases with exposure time because the telescope aperture sees higher number of (effectively) uncorrelated phase screens. The solid and dashed lines represent ξ+, and ξ−, respectively.

Fig. 7.— Simulated focal plane of LSST. We used the CCD assembly/fabrication specification in Table 1 to generate the LSST focal plane tiled by 189 CCDs.
Fig. 8.— Impact of focal plane CCD height variation on PSF. We use the ZEMAX software to obtain diffraction-limited PSFs in the absence of atmospheric turbulence. The encircled stick in the lower-left corner represents 10% ellipticity as illustrated. Note both the magnitude of ellipticity induced by the focal plane error (and aberration) and the abrupt changes across the CCD borders. The large circle shows the 3.5 m diameter field of view. The sticks outside this circle are for illustrative purpose only to demonstrate that the aberration degrades severely beyond the 1.75° boundary.
Fig. 9.— PCA eigenPSFs. The eigenPSFs were ranked by their eigenvalues with $n = 0$ representing the largest. The example shown here is derived by performing PCA on 4000 simulated PSFs. As $n$ increases, the eigenPSF tends to possess higher-frequency features. Interestingly, the first several eigenPSFs resemble the basis functions obtained by the shapelet formalism remarkably. However, asymmetry is also evident, which reveals the characteristic pattern of the data.
Fig. 10.—Simulated LSST image. We display only a $\sim 100'' \times 100''$ cutout to show the detail. The left panel image is the result prior to noise addition, about 2 mag deeper than the median depth (6000 s, $\sim 27.5$ at 5 $\sigma$) shown in the middle panel. The nominal 15 second exposure case is shown in the right panel.
Fig. 11.— Ellipticity distribution in simulated LSST images. We display “whiskers” overlaid on the LSST focal plane that we use for the input PSF generation. Apart from the magnitude, the PSF pattern is similar to the one in the case when only optical aberration and focal plane height errors are considered (Figure 8). The reduction in the magnitude demonstrates that the atmospheric turbulence mostly circularizes the PSF rather than introduces additional anisotropy. Because we simulate the sky near the zenith, the ellipticity due to the atmospheric dispersion is very small in the current case. Note that the correlation of the ellipticity change with the focal plane height variation is still visible.
Fig. 12.— Residual Ellipticity distribution. We subtracted the model ellipticity from the observed (simulated) ellipticity. Hence, the length of the whiskers shows the magnitude of the residual ellipticity ($\delta e_+, \delta e_\times$).
Fig. 13.— Ellipticity components of PSF. The blue and red dots represent the ellipticity before and after the PSF correction, respectively.

Fig. 14.— PSF ellipticity spatial correlation. We examine the correlation function $\xi_+ (r)$ for PSF ellipticity. First, PSFs are paired, and then the tangential components with respect to the line connecting the two PSFs are evaluated. The amplitude of $\xi_- (r)$ is similar to that of $\xi_+ (r)$, and is omitted for clarity. Note the dramatic reduction of the spatial correlation for residual ellipticity of the stars.
Fig. 15.— Circularization of LSST PSF from field rotation. We illustrate a toy-model observing scenario, where a same patch of the sky is visited 100 times with randomized roll angles. The focal plane height fluctuation is assumed to remain constant during the entire mission whereas the atmospheric turbulence changes with time. Post active optics residuals are small by comparison. We display only the fraction of the focal plane for easy viewing. The observed PSF ellipticity (upper right) is much smaller than seen in individual single 15 s observations (upper left). The lower left panel shows the reconstructed PSF by first performing PCA on each exposure and then stacking all model PSFs with correct application of field rotation. The residual PSF ellipticity is displayed in the lower right panel.
Fig. 16.—Same as Figure 14 but for the case that a same patch of the sky is visited multiple times with randomized roll angles. Stacking different PSF patterns reduces the correlation in intrinsic PSF (left). The residual PSF correlation function (right) remains at the similar level as in Figure 14 which is not surprising because the amplitude is already at the statistical limit.

Fig. 17.—Null test with galaxy ellipticity correlation for a single field of view and for 20,000 sq. degrees. If anisotropic PSF effects are corrected, the correlation amplitude should simply reflect the statistical noise as observed. As the number of exposures increases, the correlation amplitude goes down because the residual PSFs become more uncorrelated (systematic noise) and also the increased depth gives higher number of galaxies usable for shear measurements (statistical noise). The number density of usable galaxies for weak-lensing shear extraction in one, 10, and 100 exposures are 10, 24, and 42 galaxies per sq. arcmin, respectively. The area of the simulated image is $\sim 10^4$ sq. degrees. If we extrapolate the current result to the case, where all 20,000 sq. degrees of the area are taken, the expected amplitude of the residual galaxy shear correlation is below $\sim 10^{-8}$ (cyan).
Fig. 18.—Total (systematic + statistical) errors in galaxy shear correlation. The power-law fit gives a slope $-0.97 \pm 0.06$, consistent with the $\propto 1/n$ behavior of the statistical noise (solid line). A systematic noise, although not detected in the current 10 sq. degree simulation, will determine the minimum noise level when the nominal 20,000 sq. degree survey is completed ($\sim$ 3 billion galaxies). The dotted line shows the modification when we assume a $10^{-8}$ systematic noise floor. The expected cosmological signal is greater than $10^{-6}$ over these angular scales.
### TABLE 1
Focal plane error budget (peak-to-valley)
