ABSTRACT

We analysed 14 observations with kilohertz quasi-periodic oscillations (kHz QPOs) of the neutron star X-ray binary XTE J1701–462, the first source to show a clear transition between atoll and Z-like behaviour during a single outburst. We calculated the average cross-spectrum of both atoll and Z-phase observations of XTE J1701–462 between a reference-hard band (6.1–25.7 keV) and a subject-soft band (2.1–5.7 keV) to obtain, using a novel technique, the average time lags of the lower and upper kHz QPOs. During the atoll phase, we found that at the frequency of the lower kHz QPO the soft photons lag behind the hard ones by $18 \pm 8 \mu\text{s}$, whereas during the Z phase the lags are $33 \pm 35 \mu\text{s}$, consistent with zero. This difference in the lags of both phases suggests that in XTE J1701–462, as observed in other sources, the lags decrease with increasing luminosity. We found that for both the atoll and Z-phase observations the fractional rms amplitude increases with energy up to ~ 10 keV and remains more or less constant at higher energies. Since these changes in the variability of XTE J1701–462 occur within the same outburst, properties like the mass of the neutron star or the inclination of the system cannot be responsible for the differences in the timing properties of the kHz QPOs in the atoll and Z phase. Here, we suggest that these differences are driven by a Comptonizing component or corona, possibly oscillating in a coupled mode with the innermost regions of the accretion disc.

Key words: accretion, accretion discs – stars: neutron – X-rays: binaries – X-rays: individual: XTE J1701–462.

1 INTRODUCTION

Kilohertz quasi-periodic oscillations (kHz QPOs), fast and highly coherent variability in the emission of a source, have been detected in neutron star low-mass X-ray binaries (LMXBs) since the first kHz QPO was observed in 1996 (Strohmayer et al. 1996; van der Klis et al. 1996). Among the different types of variability observed in the emission of neutron star LMXBs (see van der Klis 2004, for a review), kHz QPOs have the highest frequency in the power density spectra (PDS), with central frequencies spanning from 250 to 1200 Hz (Méndez & Belloni 2021).

QPOs in the emission of neutron star LMXBs are characterized by three basic parameters: their central frequency, ν_{central} , their quality factor, $Q = \nu_{\text{central}}/\text{FWHM}$, where FWHM is the full width at half-maximum of the power of the QPO (see Belloni, Psaltis & van der Klis 2002), and their fractional rms amplitude, r_{rms} . Usually kHz QPOs appear in pairs in the PDS and are called, respectively, upper and lower kHz QPOs, according to their relative Fourier frequency.

Studying the phenomena behind kHz QPOs has remained of great interest due to the tight relation between the short time-scales of the variability and the dynamical time-scales of the inner accretion flow close to neutron stars (Stella, Vietri & Morsink 1999; Psaltis & Norman 2000; Psaltis 2001). Understanding the nature of kHz QPOs, and the mechanism that produces them, can potentially shed light on

to the physics of neutron stars and the study of environments under the influence of their strong gravity (see e.g. Miller, Lamb & Cook 1998b; van der Klis 2005; Psaltis 2008).

Multiple models have been proposed to explain the characteristics of kHz QPOs, however, none of them can represent all of the QPO properties simultaneously in a consistent way. Dynamical models that specifically try to explain the Fourier frequencies of kHz QPOs and relations among them are, for example: kHz QPOs as Keplerian oscillators under the influence of a rotating frame of reference (Osherovich & Titarchuk 1999; Titarchuk 2003), the sonic-point beat-frequency model (Miller, Lamb & Psaltis 1998a; Lamb & Miller 2003), kHz QPOs as resonances between the orbital and radial epicyclic relativistic frequencies in the accretion disc (Kluźniak & Abramowicz 2001), and the relativistic precession model (Stella & Vietri 1997). Deeper studies of spectral-timing properties of kHz QPOs can provide a more complete picture of the phenomena that produce the variability and its nature. For instance, by studying the correlation between the emission in different energy ranges using higher order Fourier techniques like the cross-spectrum, it is possible to constrain the emission processes involved in the variability (see Uttley et al. 2014, for a review of Fourier spectral timing techniques).

Energy-dependent time lags are among these higher order timing products used to study the X-ray variability in LMXBs. The time lags of kHz QPOs were first studied by Vaughan et al. (1997) and Kaaret et al. (1999). Both groups found that, at the frequency of the lower kHz QPOs in 4U 1608–52 and 4U 1636–53, respectively, the soft X-ray photons consistently lag behind the hard X-ray photons

* E-mail: v.peirano@astro.rug.nl

by around 25 μs .¹ Since then, spectral-timing studies have been performed on other LMXBs to measure lags more precisely, finding soft lags at the frequency of the lower kHz QPO (see e.g. Barret 2013; de Avellar et al. 2013; Troyer & Cackett 2017) and lags that are consistent with zero or slightly hard at the frequency of the upper kHz QPO (see e.g. de Avellar et al. 2013, 2016; Peille, Barret & Uttley 2015; Troyer et al. 2018, for studies of the lags of both kHz QPOs). The nature of the lags between the soft and hard X-ray bands at the QPO frequencies is still a subject of debate, with no clear interpretation of the phenomena causing them and their relation to the physics of the source.

For a long time, Comptonization has been considered to be the source of the hard X-ray component in the spectra of X-ray binaries (Thorne & Price 1975; Shapiro, Lightman & Eardley 1976; Sunyaev & Titarchuk 1980), and the interaction of soft photons with the Comptonizing region, or corona, to be a potential mechanism responsible for the observed time lags (Lee & Miller 1998). In principle, inverse Compton scattering leads to hard lags, since the most energetic photons are the ones that suffered the most number of scatterings and are therefore the ones that emerge last from the system. Soft lags are explained in Comptonization models by considering an oscillation in the temperature of the source of the soft photons produced through feedback by an oscillation in the temperature of the corona, with a fraction of the Comptonized photons returning to the soft photon source. This effect will ultimately delay the soft photons with respect to the hard photons, producing the lag that we observe (Lee, Misra & Taam 2001). Self-consistent models that consider the changes in temperature of the corona and the aforementioned feedback on to the soft photons source have been subsequently proposed, and are capable of explaining the energy-dependent fractional rms amplitude and time lags (Kumar & Misra 2014, 2016; Karpouzas et al. 2020).

Neutron star LMXBs, where kHz QPOs appear, are generally divided into two classes: Atoll and Z sources (Hasinger & van der Klis 1989), depending on the path that the LMXB traces in the colour–colour diagram (CCD). The differences in the evolution of a source in the CCD are believed to be related to the mass accretion rate on to the neutron star and to the geometry of the accretion flow (Méndez et al. 1999; Done, Gierliński & Kubota 2007). Until 2006, with the discovery of XTE J1701–462 (Remillard et al. 2006), it was considered that atoll and Z sources were two types of intrinsically different neutron star systems, with different spectral and timing behaviour (van Straaten, van der Klis & Méndez 2003; Reig, van Straaten & van der Klis 2004). However, XTE J1701–462 showed both atoll-like and Z-like behaviour during one single outburst (Homan et al. 2007; Lin, Remillard & Homan 2009a; Homan et al. 2010) becoming the first observed system to display a clear transition between the two classes. Sanna et al. (2010) studied the properties of the kHz QPOs in both phases of XTE J1701–462, and found that the quality factor and the fractional rms amplitude of both the lower and the upper kHz QPOs are consistently higher, at a given QPO frequency, in the atoll than in the Z phase (see also Barret, Bachetti & Miller 2011). Sanna et al. (2010) proposed that the spectral properties of XTE J1701–462 suggest that many of the intrinsic differences believed to exist between atoll and Z sources (e.g. magnetic field or inclination) cannot explain the differences observed in the timing properties of kHz QPOs in both phases.

The behaviour of the lag of the lower kHz QPO in atoll sources has indeed been observed to depend on energy in LMXBs, as suggested by the Comptonization with feedback model, becoming softer with increasing energy (see e.g. Troyer et al. 2018). Peirano & Méndez (2021) studied eight atoll LMXBs and found that the slopes of the best-fitting linear model to the time-lag spectrum and the total rms amplitude of the lower kHz QPO exponentially decrease with increasing luminosity of the source, suggesting that the mechanism responsible for the lower kHz QPO depends on the properties of the corona. Peirano & Méndez (2021) also found that for the upper kHz QPO the slope of the time-lag spectrum is consistent with zero for all sources, concluding that the upper kHz QPOs have a different origin to the lower kHz QPOs (see e.g. de Avellar et al. 2013; Peille et al. 2015). The transient source XTE J1701–462 offers an unprecedented perspective if studied in a similar way, considering that during the transition from Z-like to atoll-like behaviour, XTE J1701–462 also experimented a significant change in luminosity (Sanna et al. 2010).

To date, no study of the energy-dependent lags and their dependence on luminosity has been performed for XTE J1701–462. In this paper, we combine previous studies of this source and other atoll LMXBs, with an analysis of the spectral-timing properties of the kHz QPOs observed during the 2006–2007 outburst of XTE J1701–462. We study and compare the energy dependence of the fractional rms amplitude, intrinsic coherence and lags at the frequency of the kHz QPOs in the atoll and Z phases of the outburst of XTE J1701–462. We also study the dependence of the average lags on the luminosity of the source, putting this result into context with the behaviour observed in other LMXBs. In Section 2, we describe the observations and the methods used in the analysis of the data, in Section 3 we show the results of such analysis, and in Section 4 we discuss the scientific implications of these results.

2 OBSERVATIONS AND DATA ANALYSIS

2.1 Observations

There are 866 observations in the public archive of the Rossi X-ray Timing Explorer (RXTE; Bradt, Rothschild & Swank 1993) of the source XTE J1701–462 collected using the Proportional Counter Array (PCA; Jahoda et al. 2006). From these observations here, we studied the 14 observations that have kHz QPOs in their power spectra. We selected these observations using the criteria described in Sanna et al. (2010).

Following Homan et al. (2010), we considered that XTE J1701–462 was in the Z phase of the outburst from the first time it was observed (Remillard et al. 2006) in 2006 January, until 2007 April. After this date, and until the source went into the quiescent phase, we considered XTE J1701–462 to be in the atoll phase of the outburst. Following this criterion, there are six observations in the Z phase of the source (ObsIDs: 93703-01-02-04, 93703-01-02-05, 93703-01-02-08, 93703-01-02-11, 93703-01-03-00, and 93703-01-03-02) and eight observations in the atoll phase (ObsIDs: 91442-01-07-09, 92405-01-01-02, 92405-01-01-04, 92405-01-02-03, 92405-01-02-05, 92405-01-03-05, 92405-01-40-04, and 92405-01-40-05) that show kHz QPOs. Hereafter, we will refer to the observations during the Z phase of XTE J1701–462 as Z observations, and to the observations during the atoll phase as atoll observations.

2.2 Fourier timing analysis

To study the kHz QPOs we computed Leahy-normalized PDS of each observation, using event-mode data with at least 250 μs

¹When the soft photons lag behind the hard ones, the lags are called soft. When the hard photons are the ones lagging behind the soft ones, the lags are called hard.

time resolution, covering the full energy range of the instrument (nominally 2–60 keV). For some Z observations, event-mode data were not available for the entire energy range; in these cases, we used a combination of event-mode data and binned data covering the full PCA band. For each observation, we calculated PDS every 16-s data segments, yielding a frequency range from 0.0625 to 2048 Hz. Finally, we averaged all the 16-s PDS to produce a single PDS per observation.

A multi-Lorentzian model plus a constant accounting for the Poisson level has been consistently used to describe the shape of the PDS of LMXBs (e.g. Nowak 2000; Belloni et al. 2002; Pottschmidt et al. 2003; Ribeiro et al. 2017). This model describes well the shape of the variability present in different types of sources, but is independent of the underlying physics that cause them, making it specially fit to compare the variability behaviour without making assumptions about the nature of the mechanism that produces the oscillations. The different components of the variability in the PDS can be labelled considering the strength, width and central frequency of the Lorentzian functions used to fit them (e.g. van Straaten et al. 2002). We used the convention L_ℓ and L_u to label the lower and upper kHz QPOs, respectively. For a more detailed review of different kinds of variability observed in X-ray binaries, see van der Klis (2004).

We used a Lorentzian model with one or two Lorentzian functions plus a constant to fit and characterize the kHz QPOs in the PDS of observations in both the atoll and Z phase of XTE J1701–462. For the atoll observations, we fitted the PDS between 600 and 900 Hz, rebinning the data by a factor of 64; and for the Z observations, we fitted the PDS between 400 and 1200 Hz, rebinning the data by a factor of 128. Since we observed only one kHz QPO during the atoll phase, which Sanna et al. (2010) identified as the lower kHz QPO, we used only one Lorentzian function to characterize it during the fit. In the Z phase we observed two simultaneous kHz QPOs, from which we identified the one at the lowest central frequency as the lower kHz QPO and the one at the highest central frequency as the upper kHz QPO. For the Z observations, we used two Lorentzian functions to describe each kHz QPO during the fit. Inspection of the PDS of observations in both the atoll and Z phases showed that the lower kHz QPOs has a higher quality factor in the atoll phase than in the Z phase, confirming the results of Sanna et al. (2010).

We found that, in the PDS of the atoll observations, the central frequency of the lower kHz QPOs varies considerably throughout the length of one entire observation. To trace these changes in central frequency, we constructed dynamical power spectra of the atoll observations using 16-s segments PDS and assigning a unique L_ℓ central frequency to each segment. When necessary, we combined multiple contiguous 16-s PDS until it was possible to identify a unique central frequency value for those segments combined. Using these central frequencies, we split every PDS into eight different frequency selections, with limits in frequency listed in Table 4. We shift-and-added (Méndez et al. 1998) together every 16-s PDS of each frequency selection into one unique PDS, shifting the kHz QPOs to a frequency in the centre of the corresponding frequency selection.

In contrast, when analysing the PDS of the Z observations, because the QPOs are weaker and broader than in the atoll phase, it is not possible to significantly detect changes in the central frequency of the kHz QPOs within the length of a single observation. For this reason, we analysed the PDS of every full observation during the Z phase separately (see Table 3). In Figs 1 and 2, we show examples of the PDS from two Z observations (91442-01-07-09, with a more significant lower kHz QPO, and 92405-01-02-03, with a more significant upper kHz QPO) and the PDS of the 830–840 Hz frequency selection of the atoll observations.

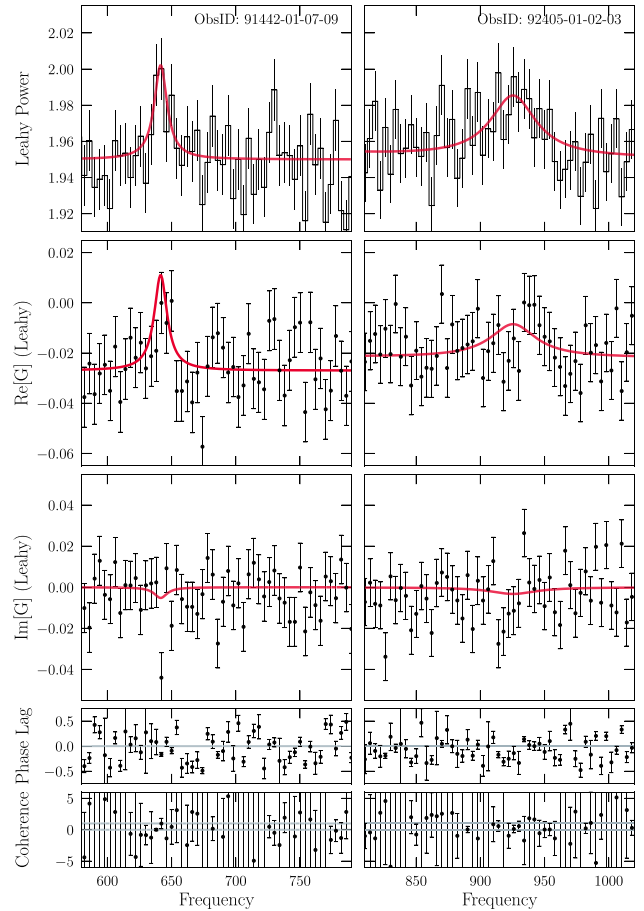

Figure 1. *Top panel:* PDS of the observations 91442-01-07-09 and 92405-01-02-03 of XTE J1701–462 during its Z phase. The fitted Lorentzian function to the kHz QPO is shown in red on top of the histogram. *Second and third panels:* Real and imaginary parts of the cross-spectrum of the two Z observations. The red solid line shows the joint best-fitting Lorentzian functions. *Fourth and fifth panels:* Phase lag and intrinsic coherence as a function of Fourier frequency. In the fourth panel, the grey solid line indicates zero phase lag. In the fifth panel, the grey solid lines indicate coherence equal to one (perfect coherence between signals) and equal to zero (completely incoherent signals).

To calculate the average cross-spectra, $G = \text{Re}[G] + i\text{Im}[G]$, we computed complex Fourier transforms for both the atoll frequency selections and the Z observations in two different bands: a reference (hard) band and a subject (soft) band (see Table 1 for the limits in *RXTE* channels and equivalent energy of the bands that correspond to the Epoch 5 of the instrument, as all our observations were performed towards the end of the *RXTE* mission). Equivalently to the atoll PDS procedure described in the previous paragraph, we calculated the atoll complex Fourier transforms of each frequency selection in Table 4 shift-and-adding (using the already defined central frequencies) 16-s segments with a time resolution of 250 μs , and a minimum and maximum Fourier frequency of 0.0625 and 2048 Hz, respectively. Examples of real and imaginary parts of these averaged cross-spectra are shown in the second and third panels of Figs 1 and 2, for the atoll and Z phase, respectively. The errors reported for both the real and imaginary parts of the cross-spectra are given by equation (13) in Ingram (2019).

Using these averaged cross-spectra and following the procedure in Nowak et al. (1999), we calculated the phase lag and intrinsic

Figure 2. *Top panel:* Shifted-and-added PDS of XTE J1701–462 during its atoll phase, for the observations where the frequency of the lower kHz QPO was between 830 and 840 Hz. *Second and third panels:* Real and imaginary parts of the cross-spectrum of the atoll frequency selection. The red solid line shows the joint best-fitting Lorentzian function. *Fourth and fifth panels:* Phase lag and intrinsic coherence as a function of Fourier frequency. In the fourth panel, the grey solid line indicates zero phase lag. In the fifth panel, the grey solid lines indicate coherence equal to one (perfect coherence between signals) and equal to zero (completely incoherent signals).

Table 1. Energy bands and channel ranges for the cross-spectra, time/phase lags, and intrinsic coherence computations. The energy-channel conversion corresponds to the Epoch 5 of the instrument.

Subject <i>S</i>	0–13	2.1–5.7

coherence as a function of the Fourier frequency for each phase (bottom panels in Figs 1 and 2). Considering that we use the hard band as the reference band, positive values of the lags represent the soft photons lagging the hard ones, while negative values represent hard photons arriving after the soft ones.

2.3 Average phase lag of the kHz QPOs

To calculate the time and phase lags of kHz QPOs it is common to select a frequency range (using, for example, the FWHM as criterion)

and average the frequency-dependent real and imaginary parts of the cross-spectrum of an observation over this frequency range (see e.g. de Avellar et al. 2013; Troyer et al. 2018). This approach gives an accurate enough value when the lag is significant enough in the cross-spectrum, which is the case for the lower kHz QPO in the atoll observations of XTE J1701–462, but it can be a limitation when studying the Z observations, where the kHz QPOs are less significant and frequency-dependent lags are consistent with zero.

In this paper, we applied a novel technique to calculate the average lags of the lower and upper kHz QPOs of XTE J1701–462, considering the entire region in the PDS where the QPO is present. We computed the average lag of the kHz QPOs directly from a joint multi-Lorentzian fit to the real and imaginary parts of the cross-spectra of each phase, calculated as described in Section 2.2. For the Z phase, we jointly fitted the cross-spectra from all Z observations (both linked and separately) fixing the values of the central frequency and the FWHM to the corresponding best-fitting parameters that describe the kHz QPOs in the Z-phase PDS (see Table 3). To directly obtain the average lags from the fit, we allowed the normalization of the real part and the phase lag to vary and computing the normalization of the imaginary part as $\text{Im}[G] = \text{Re}[G]\tan(\Delta\phi)$. This procedure is justified because the power in the full band is equal to the sum of the square of the real and imaginary parts of the Fourier transform of the full band light curve, and the signals in the two bands used to calculate the cross-spectrum are highly correlated in the frequency range of the QPOs. Because this method assumes that the lags in the frequency range over which the QPO is significant are constant, our procedure takes the full QPO profile to measure the lags.

For the Z observations 91442-01-07-09 and 92405-01-01-02, we only included the lower kHz QPO in the fit, as the upper kHz QPO is not significant in the PDS. Similarly, for the observation 92405-01-01-04 we considered only the upper kHz QPO in the fit, as the lower kHz QPO is not significant in the PDS (see Sanna et al. 2010). For the atoll phase, we followed a similar procedure to the one of the Z phase, but we used the cross-spectra of each frequency selection, instead of the individual atoll observations, and the corresponding best-fitting parameters to the PDS (see Table 4) to perform the joint fit of the real and imaginary parts of the cross-spectra.

In all the fits, we considered the so-called channel cross-talk (see section 2.4.2 in Lewin, van Paradijs & van der Klis 1988), a consequence of deadtime producing correlation between energy channels, by adding a constant function to the multi-Lorentzian model, that varies independently while fitting both the real and imaginary parts of the cross-spectrum. We find that the constant component of the imaginary part is consistent with zero for all fits, which is as expected since the channel cross-talk only contributes to the real part of the cross-spectrum.

The technique we used in this paper makes the lag comparison between the atoll and Z phases of XTE J1701–462 consistent, avoiding bias by selecting an arbitrary frequency range in the cross-spectrum related to the FWHM of the QPO, given that the FWHM of the QPO in Z and atoll phases is significantly different (Sanna et al. 2010).

2.4 Energy-dependent rms

Additionally, we calculated the PDS of both atoll and Z observations for a set of energy ranges in order to study the fractional rms spectrum of the QPO. We selected the energy ranges to be as close as possible to the ones used in Ribeiro et al. (2019), where they defined the channel limits considering the drift in energy-to-channel relation of the ranges used in de Avellar et al. (2016). While for the atoll

Table 2. Energy and channel equivalent ranges of the bands used in the calculation of the fractional rms amplitude. These ranges were selected to be as close as possible to the ones defined by Ribeiro et al. (2019). The energies correspond to the Epoch 5 of the instrument.

Atoll phase		Z phase	
Channel range	Average energy (keV)	Channel range	Average energy (keV)
7–11	4.2	0–13	3.9
12–15	6		
16–21	8	14–35	10.5
22–25	10.2		
26–35	12.7		
36–41	16.3	36–41	16.3
42–49	18.9	42–49	18.9

observations we were able to use exactly the same energy ranges as in Ribeiro et al. (2019), in the Z observations the ranges had to be adapted due to the data structure of the observations. The limits of the energy ranges used in this paper are given in Table 2, where the equivalent channel ranges correspond to the Epoch 5 of the instrument like in Table 1. Again these PDS were calculated using the same shift-and-add procedure described previously to obtain one single PDS per phase and energy range, with a Fourier frequency range from 0.0625 to 2048 Hz.

To calculate the fractional rms amplitude, we fitted the high-frequency region (frequencies higher than 400 Hz) of the PDS calculated in each energy band in Table 2 with either one – for the atoll phase – or two – for the Z phase – Lorentzian functions plus a constant to account for the Poisson noise. We considered the integral power obtained from the fit of the Lorentzian function as equivalent to the total power at the frequency of the kHz QPO, P_{QPO} . The fractional rms amplitude in per cent units is then given by,

$$\text{rms} = 100 \sqrt{\frac{P_{\text{QPO}}}{C_S + C_B}} \left(\frac{C_S + C_B}{C_S} \right) \text{ per cent}, \quad (1)$$

where C_S is the source count rate – equivalent to the total count rate minus the background count rate, C_B .

The errors reported for the rms calculations correspond to 1σ , every time the kHz QPOs were detected with at least 3σ significance. In those cases in which the power of the QPO was consistent with zero or not significant enough when calculating the rms, we report the 95 per cent confidence upper limit, which we calculated by fixing both the central frequency and the width of the Lorentzian function to the values we obtained from the fit on the entire energy range (in Table 3 for the Z phase and Table 4 for the atoll phase).

3 RESULTS

In this section, we show the results of the Fourier analysis of the XTE J1701–462 observations during the atoll and Z phases of the outburst. In Section 3.1, we show the PDS of the source during both phases and the results of the fitting procedure to identify the kHz QPOs. In Section 3.2, we show the analysis of the phase lags and intrinsic coherence of the signal as a function of Fourier frequency in the atoll and Z phases. In Section 3.3, we examine the behaviour of the phase lags versus QPO frequency for each observation during the Z phase and for each frequency selection of the atoll phase. In Section 3.3, we study the relation between the average time lags of the lower kHz QPOs during the atoll and Z phase of XTE J1701–462 and the luminosity of the source, comparing our results with other

atoll sources. Finally, in Section 3.5, we explore the fractional rms amplitude dependence upon energy in each phase of the outburst.

3.1 QPO identification and properties

To distinguish between the lower and the upper kHz QPO, we adopted the kHz QPO identification used in Sanna et al. (2010). In the Z phase of XTE J1701–462, the identification is straightforward: two peaks appear in the PDS at high frequencies, one corresponding to the lower and one to the upper kHz QPO. In contrast, during the atoll phase only one peak is significant enough in each observation, corresponding to the lower kHz QPO (see fig. 2 in Sanna et al. 2010, where a second higher frequency peak appears after applying the shift-and-add method to all atoll phase observations combined).

In the top panels of Figs 1 and 2, we show the resulting best-fitting Lorentzian model to the PDS of two Z observations (91442-01-07-09 and 92405-01-02-03) and one frequency selection (between 830 and 840 Hz) of the atoll observations, respectively, as examples of the analysis performed over all the observations of XTE J1701–462. The resulting best-fitting parameters to each Z observation PDS are listed in Table 3, while the best-fitting parameters to each frequency selection PDS of the atoll observations are listed in Table 4.

3.2 Phase lag and coherence

In Tables 3 and 4, the best-fitting values of the phase lag, calculated following the procedure described in Section 2.3, of both lower and upper kHz QPOs in the Z and atoll phases, are shown. In the atoll phase, the average phase lag over all the selections of the lower kHz QPO frequency is 0.08 ± 0.04 radians, which means that the soft photons lag the hard ones by approximately $16 \mu\text{s}$ at this frequency. In the Z phase, the average phase lag at the frequency of the lower kHz QPO is 0.05 ± 0.15 radians and at the frequency of the upper kHz QPO is 0.25 ± 0.16 radians, both consistent with zero. The best-fitting Lorentzian functions to the real and imaginary parts of the cross-spectra of two Z observations and one frequency selection of the atoll observations are shown in the middle panels of Figs 1 and 2. Since the data from each observation in the Z phase and frequency selection in the atoll phase look very similar, we show these three examples to illustrate the analysis process.

In the bottom panel of Fig. 2 is apparent that the coherence is well constrained (small error bars) around the central frequency of the QPO in the atoll phase, within a close to symmetric frequency range around ~ 835 Hz. Immediately outside of this frequency range, the errors of the coherence increase noticeably in the plot. In the bottom panels in Fig. 1, while we also observe smaller errors in coherence at the central frequency of the kHz QPOs, the frequency range at which the coherence appears more constrained in the Z phase is narrower and less symmetric than it is in the atoll phase. This difference in the behaviour of the coherence of the signal, and considering that during the Z phase the kHz QPOs appear weaker and broader than during the atoll phase, makes the technique we used here to calculate the lags (see Section 2.3) especially suitable to appropriately compare the two phases of XTE J1701–462.

3.3 Phase lags and QPO frequency

In Fig. 3, we show the relation between the phase lag of the lower and upper kHz QPOs of XTE J1701–462 and the QPO frequency, using the data in Tables 3 and 4. The lags of the lower kHz QPO during the atoll phase of XTE J1701–462 show a marginal dependence on QPO frequency [consistent with the results of Barret (2013) and de Avellar

Table 3. Properties of the kHz QPOs detected in the Z phase of XTE J1701–462. The fractional rms amplitude was calculated over the full energy range of the instrument, between 2 and 60 keV. The phase lag, between the reference-hard band and the subject-soft band in Table 1, was calculated as described in Section 2.3, first for each Z observation individually and then in a joint fit of all Z observations to obtain a unique value for the Z phase of the source. Subscript letters ℓ and u denote lower and upper kHz QPOs, respectively.

et al. (2013)], however, considering the errors of the measured lags, their overall trend remains constant with increasing QPO frequency. The lags of the lower and upper kHz QPOs during the Z-phase observations show no clear dependence upon QPO frequency. The diamonds in the plot show the average lags we obtained from the joint fit of the cross-spectra of each phase (as described in Section 2.3). The value of the frequency for these average lags corresponds to the mean frequency of all the data points of each kHz QPO, and is meant to be used only as a reference.

3.4 Average time lags and luminosity

In Fig. 4, we show the dependence of the average time lag of the lower kHz QPO in the atoll and Z phases of XTE J1701–462 upon luminosity, and compare it to the data of the eight atoll sources in Peirano & Méndez (2021). The solid lines in the figure represent the best-fitting exponential model, $\langle \Delta t \rangle^\ell = A e^{-(L/L_{\text{Edd}})/\alpha}$, to only the eight atoll sources in Peirano & Méndez (2021) (in grey), with $A = 36.5 \pm 7.1 \mu\text{s}$ and $\alpha = 0.09 \pm 0.03$; and to the same eight atoll sources plus XTE J1701–462 in both phases (in black), with $A = 36.5 \pm 6.2 \mu\text{s}$ and $\alpha = 0.09 \pm 0.03$. From Fig. 4, it is clear that, as the luminosity increases, the average time lags decrease exponentially for the eight atoll sources in Peirano & Méndez (2021) and XTE J1701–462 in the atoll phase. In the Z phase of XTE J1701–462, the time lags are not as well constrained as in the atoll phase, however, the residuals show that the lags are consistent with the same trend of the atoll

sources in Peirano & Méndez (2021) and the atoll observations of XTE J1701–462.

We extracted the luminosity of XTE J1701–462 during its Z and atoll phases from fig. 5 in Sanna et al. (2010). To calculate the luminosity, Sanna et al. (2010) used a distance of 8.8 kpc, estimated by Lin et al. (2009b) using the Type-I X-ray bursts that occurred during the 2006–2007 outburst of XTE J1701–462, and the 2–50 keV flux from the source normalized by $L_{\text{Edd}} = 2.5 \times 10^{38} \text{ erg s}^{-1}$, which corresponds to the Eddington luminosity of a 1.9 M_\odot neutron star accreting gas with cosmic abundance.

3.5 Fractional rms amplitude versus energy

Sanna et al. (2010) studied the dependence of the fractional rms amplitude of the kHz QPOs upon the QPO frequency of XTE J1701–462, both in the atoll or Z phases, and showed that the fractional rms amplitude of the lower kHz QPO is consistently higher in the atoll than in the Z phase (see fig. 4 in Sanna et al. 2010). Similarly, Sanna et al. (2010) found that the quality factor of the lower kHz QPO is significantly higher in the atoll than in the Z phase.

In Fig. 5, we show the fractional rms amplitude of both kHz QPOs as a function of energy for the atoll and Z phases, for the different energy bands defined in Table 2. In the figure, the error bars represent the 1σ uncertainty and the arrows represent the 95 per cent confidence upper limits. In Fig. 5, it is apparent that the fractional rms amplitude

Figure 3. Phase lag of the lower (red squares) and upper (purple triangles) kHz QPO of XTE J1701–462 Z observations and the lower (blue circles) kHz QPOs of XTE J1701–462 atoll observations as a function of QPO frequency. The error bars of the atoll phase lower kHz QPO lag represent the frequency bins ranges from Table 4. The diamonds show the average lag value of the lower and upper kHz QPOs in the Z phase and the lower kHz QPO in the atoll phase, with frequency equal to the mean frequency of each data group. The solid grey line indicates the zero lag.

Figure 4. Average time lag of the lower kHz QPO as a function of luminosity. The grey circles correspond the atoll LMXBs from Peirano & Méndez (2021), the blue diamond corresponds to XTE J1701–462 during its atoll phase and the red diamond to XTE J1701–462 during its Z phase. The solid black line indicates the best-fitting exponential model to the data. The solid grey line indicates the best-fitting exponential model to the atoll sample in Peirano & Méndez (2021). The value of the luminosity of XTE J1701–462 during its atoll and Z phases was extracted from fig. 5 in Sanna et al. (2010). Residuals, (data-model)/error, are also shown.

MNRAS **513**, 2804–2813 (2022)

Figure 5. Fractional rms amplitude as a function of energy for the atoll phase lower kHz QPO (blue circles) and the Z phase lower (red squares) and upper (purple triangles) kHz QPOs of XTE J1701–462. The solid lines indicate the best-fitting broken-line model, where the break energy, E_{break} , is marked by the vertical grey line. The arrows indicate upper limits.

of the lower kHz QPO is consistently higher in the atoll than in the Z phase for all energies. In the Z-phase observations, the dependence of the fractional rms amplitude upon energy for the lower and the upper kHz QPOs has no apparent significant differences. In all cases,

Table 5. Parameters of the broken-line model fit to the fractional rms amplitude as a function of energy at the frequency of the kHz QPOs detected in both the atoll and Z phase of XTE J1701–462, with E_{break} linked and equal for all QPOs and m_2 fixed to zero.

	Atoll phase L_ℓ	Z phase L_ℓ	L_u
m_1	1.48 ± 0.07	0.33 ± 0.04	0.38 ± 0.04
m_2		Fixed to 0	
E_{break}		9.26 ± 0.76	

the fractional rms amplitude increases with energy up to a certain value and then remains constant for higher energies.

To study the shape of the relation between the fractional rms amplitude and the photon energy, we fitted a broken line model to the data, given by the following equation:

$$\text{rms}(E) = \begin{cases} m_1 E, & \text{if } E < E_{\text{break}} \\ m_2 E + (m_1 - m_2)E_{\text{break}}, & \text{if } E \geq E_{\text{break}}, \end{cases} \quad (2)$$

where E_{break} is the break energy (up until which the rms value increases), and m_1 and m_2 are the slopes of the lines before and after the break energy, respectively.

We first performed a joint fit of the fractional rms amplitude data of all kHz QPOs (the lower kHz QPO in the atoll phase, and the lower and upper kHz QPOs in the Z phase) using the model given by equation (2) and linking both E_{break} and m_2 for all the data sets. This fit yielded a reduced chi-squared $\chi^2_v = 1.037$ for 9 degrees of freedom. Since the resulting best-fitting value of $m_2 = 0.27 \pm 0.13$ was not significantly different from zero, we performed a new fit linking only E_{break} and fixing m_2 to zero for all data sets. This new fit yielded a reduced chi-squared $\chi^2_v = 1.400$ for 10 degrees of freedom. The F -test between the broken-line model with E_{break} and m_2 linked and the broken-line model with only E_{break} linked and $m_2 = 0$ gives a probability of 0.06. In other words, there is no statistically significant advantage in considering the slope after the break m_2 different from zero in the fit.

The best-fitting parameters of the fit with E_{break} linked and m_2 fixed to zero are given in Table 5 and the resulting fit is shown in Fig. 5 for both the Z and atoll phases. From this figure, and the values in Table 5, we found that the difference between the slope before the break m_1 of the lower kHz QPO in the atoll and Z phases has a significance of $\sim 14\sigma$, which means that the dependence upon energy of the fractional rms amplitude of the lower kHz QPO is significantly different for both phases. Similarly, we contrasted the slope before the break for the lower and upper kHz QPOs in the Z phase only, finding that there is no significant difference between them.

In the fit of the fractional rms amplitude versus energy, we used the 1σ error as the uncertainty of the variable to fit. When the fitted Lorentzian in the corresponding energy band PDS yielded a negative integral power of the QPO in comparison with the Poisson level, we fixed the fractional rms amplitude to zero and we considered the uncertainty to be the 95 per cent confidence upper limit to perform the fit. In the cases where the integral power of the QPO was positive, but not significantly different from zero, we considered the original fitted value of the integral QPO power and its 1σ error as valid during the fit.

The binning in time we performed when calculating the PDS to have a Nyquist frequency of 2048 Hz reduces the variability dominantly at high frequencies (see section 4.3 van der Klis 1989), which can be relevant for the frequency ranges at which kHz QPOs are observed. Equation (4.7) in van der Klis (1989) gives

the correction factor for this effect as follows:

$$\beta = \frac{\pi \nu T / N}{\sin \pi \nu T / N} = \frac{\pi \nu / 2 \nu_{\text{Nyq}}}{\sin \pi \nu / 2 \nu_{\text{Nyq}}}, \quad (3)$$

where ν is the frequency of the QPO, T is the length of the observation, N is the number of power spectra binned together when calculating the PDS, and $\nu_{\text{Nyq}} = 1/2\Delta T$ is the Nyquist frequency of the PDS, with $\Delta T = T/N$, the length of each data segment. The correction factor, for $\nu_{\text{Nyq}} = 2048$ Hz, of the lower and upper kHz QPO in the Z observations is ~ 1.04 and ~ 1.09 , respectively, and of the lower kHz QPO in the atoll observations is ~ 1.07 . These values are all within the errors reported in Fig. 5, therefore not affecting the results we present here.

4 DISCUSSION

We studied the timing properties of the kHz QPOs of the transient neutron star LMXB XTE J1701–462 and characterized, for the first time, the frequency-dependent QPO lags simultaneously for the atoll and Z phases of the source. We calculated, using a novel technique, the average lags at the frequency of the QPO both in the Z and atoll phases and discovered that during the atoll phase the time lags of the lower kHz QPO are soft, with the soft photons lagging the hard ones by around 16 μs . During the Z phase, the lags of both the lower and upper kHz QPOs are consistent with zero. We also found that the intrinsic coherence of the signal is more well constrain at the frequency of the lower kHz QPO in the atoll than in the Z phase.

Additionally, we explored the behaviour of the phase lags at different QPO frequencies and observed that while the lags of the lower kHz QPO in the atoll observations of XTE J1701–462 have a slight dependence upon QPO frequency, the phase lags of both the lower and upper kHz QPOs in the Z observations do not. We also studied the dependence of the average time lags of the lower kHz QPO upon luminosity during both the Z and atoll phases. We found that the average lags follow the same trend with luminosity of other atoll neutron star systems, with the lags decreasing exponentially with increasing luminosity. Finally, we studied the fractional rms amplitude dependence upon energy of the lower and upper kHz QPOs in each phase of XTE J1701–462 and discovered that, as observed in other LMXBs, the fractional rms amplitude of the lower kHz QPO increases with energy up to approximately 10 keV and then remains constant at higher energies.

4.1 Soft lags and the corona

During the atoll phase of XTE J1701–462 we observe more clearly that, in the presence of the lower kHz QPO, the photons in the soft band, between 2.1 and 5.7 keV, lag behind the photons in the hard band, between 6.1 and 25.7 keV. Inverse Compton scattering with feedback on to the soft photon source (see Lee et al. 2001; Kumar & Misra 2016; Karpouzas et al. 2020) can explain these soft lags in a scenario where it is not the disc, but the corona that is responsible for the variability we observe. Indeed, the corona dominates the X-ray emission at high energies, where we observe the variability reaching its maximum amplitude (see Fig. 5, where the fractional rms amplitude for the lower kHz QPO in the atoll phase of XTE J1701–462 reaches its maximum at around 10 keV).

Inverse Compton scattering occurs in the corona when electrons transfer energy to photons coming from the soft energy source in an LMXB (either the disc or the surface of the neutron star), producing a delay in the emission of hard photons, with higher energies. A fraction of these Comptonized photons return to the disc and are

emitted again at lower energies and later times, producing the soft lags we observe (Lee et al. 2001; Karpouzas et al. 2020). This model not only explains the soft lags we see in the lower kHz QPOs in our data, but also can describe the difference in sign of the lags of the upper kHz QPOs in other sources (see e.g. de Avellar et al. 2013; Peille et al. 2015) and the behaviour of the lags of other variability components (see e.g. Miyamoto et al. 1988; Ford et al. 1999).

4.2 Variability in the Z and atoll phases

We observe multiple differences between the variability properties of the kHz QPOs in the Z and atoll phases of XTE J1701–462. More evident in Fig. 5 is the consistently higher fractional rms amplitude of the lower kHz QPO in the atoll phase of the source when compared with the lower and upper kHz QPOs present in the Z phase. This discrepancy in the timing properties of the kHz QPOs in both phases of XTE J1701–462 are comparable with observed differences in the variability of atoll and Z LMXBs. For example, Méndez (2006) studied 12 LMXBs and found that in the Z sources of his sample the maximum rms amplitude of both kHz QPOs and the maximum quality factor of the lower kHz QPO are consistently lower than in the atoll sources.

In Figs 1 and 2, we also observe a difference in the intrinsic coherence of the signal at the frequency of the QPOs, between both phases. In the figures, it is clear that the frequency range within which the uncertainty of the intrinsic coherence is smaller, is not as well constrained in the Z than in the atoll observations. During the atoll phase of the source, the intrinsic coherence remains visibly more stable when the QPO is present in the PDS. The difference in the intrinsic coherence of the signal, although consistent with other LMXBs (see e.g. Barret et al. 2011), makes using it as a criterion to measure the average lag over a frequency range, and compare both phases consistently, difficult. Here, we used a novel technique to calculate the average lags at the frequency of the QPO (see Section 2.3) that allows for a more consistent comparison between the atoll and Z phases. In this method, we use the Lorentzian function that describes the kHz QPOs in the PDS to find the amplitudes of the real and imaginary parts of the cross-spectra, without averaging them over a certain arbitrary frequency range defined by the coherence of the signal (which will, particularly in the case of the Z observations, lead to inconsistencies in the obtained lags).

We also studied the behaviour of the phase lags of the lower and upper kHz QPOs with respect to the QPO frequency, for both the atoll and Z phases. In Fig. 3, we observe a weak dependence upon QPO frequency of the lags of the lower kHz QPO in the atoll phase. Despite the fact that the trend of these lags is also consistent with a constant model, the slight increase and then decrease with frequency we see in Fig. 3 is consistent within errors with the relations shown by Barret (2013) and de Avellar et al. (2013) for the lags of the lower kHz QPOs in 4U 1608–522 and 4U 1636–53, respectively. The phase lags of the lower and upper kHz QPOs in the Z phase do not show a trend with QPO frequency in Fig. 3, which is also in agreement with previous studies where it has been shown that the lags of the upper kHz QPO are constant with QPO frequency (see e.g. de Avellar et al. 2013; Peille et al. 2015).

The large error of the average lags of the Z observations that we obtained using the technique described in Section 2.3, together with the differences in the behaviour of the intrinsic coherence of the signal in the Z and atoll phases and the lower fractional rms amplitude of the variability in the Z phase (already observed by Sanna et al. 2010), suggest that the mechanism responsible for the kHz QPOs is affected

during the transition from a Z-like source to an atoll-like source of XTE J1701–462.

Differences in the properties of kHz QPOs of atoll and Z sources, like the ones we observe before and after the transition of XTE J1701–462, are believed to be related to the geometry of the accretion flow and the mass accretion rate of the source (see Méndez 2006, for a more detailed discussion). Sanna et al. (2010) discarded changes in the magnetic field, neutron star mass, and inclination of the system as responsible for the variations we observe in the high-frequency variability in our data, as these changes cannot occur within the time-scale of the transition of XTE J1701–462. Furthermore, Sanna et al. (2010) studied how the maximum quality factor and rms amplitude of the lower kHz QPOs in both the Z and atoll phases of XTE J1701–462 depended upon the luminosity of the source and found that this relation follows the trend found by Méndez (2006) for a sample of 12 atoll and Z LMXBs. These results characterize XTE J1701–462 as a unique case to study, as the behaviour of its variability follows the relations observed in other sources, while many of the fundamental properties of the source remain constant.

4.3 Lags and the atoll- and Z-phase luminosity

Peirano & Méndez (2021) studied the relation between the slope of the time-lag spectrum, m , and the luminosity of the source for eight atoll LMXBs and found that m decreases exponentially with increasing luminosity. These authors found a similar relation between the average time lags and the luminosity of the source. Considering these results, it is interesting to check whether the relation of the average time lags and luminosity holds for the Z and atoll phases of XTE J1701–462.

In Fig. 4, we combine the data from Peirano & Méndez (2021) with the data of XTE J1701–462, using the luminosities for the Z and atoll phases of XTE J1701–462 given by Sanna et al. (2010). In the top panel of the figure, it is apparent that XTE J1701–462, during its atoll phase, follows the trend of the other atoll sources very closely. Indeed, the black solid line, that represents the best-fitting exponential model to all data points, lies almost exactly over the grey solid line that represents the best-fitting exponential model to only the atoll sources in Peirano & Méndez (2021). During the Z phase, the average lags have a large uncertainty; however, in the bottom panel of Fig. 4 it is apparent that during the Z phase of XTE J1701–462 the relation between the average lags of the lower kHz QPO and luminosity also holds.

Peirano & Méndez (2021) suggested that the similar relations between the slope of the time-lag spectrum and the total rms amplitude with the luminosity of the source (both decrease exponentially with increasing luminosity) imply that there is one single property of the system in these LMXBs that drives the behaviour of the variability. Since we observe a similar dependence upon luminosity of the average lags in both Z and atoll phases of XTE J1701–462, we can conclude that a similar effect is taking place in this source while it transitioned from one phase to the other. This relation suggests that it is the corona that is responsible for the changes we observe in the variability, as its contribution in the energy spectrum changes with luminosity.² This scenario fits with the inverse Compton scattering model with feedback on to the soft photon source (see Lee et al. 2001; Kumar & Misra 2016; Karpouzas et al. 2020) we described in Section 4.1, as in this model is also the corona the one that drives the

²We use here the luminosity as a proxy for the properties of the corona as done in Peirano & Méndez (2021).

properties of the variability. Our results confirm what was suggested in Peirano & Méndez (2021), where they described the mechanism that modulates the kHz QPOs as a coupled mode of oscillation between the corona and the disc. In this ‘coupled oscillation mode’, changes in the luminosity – if used as a proxy of the properties of the corona – when XTE J1701–462 transitions from the Z to the atoll-like behaviour, the fractional rms amplitude and the lags of the kHz QPOs should decrease, exactly as we observe in our data.

Studies of the behaviour of time and phase lags with luminosity for Z neutron star LMXBs, that are located in the high-luminosity end of Fig. 4, could help elucidate the real nature of the mechanism responsible for the high-frequency variability we observe. To date no systematic study of the timing properties of Z sources has been performed, but the results shown in this paper suggest that the average lags of the lower kHz QPO should decrease exponentially as the luminosity increases. A more in-depth analysis of the results presented in this paper, through the glass of the model described in Karpouzas et al. (2020) and García et al. (2021) could also help understand the changes in the geometry of the accretion flow that can be driving the changes in the properties of the variability when XTE J1701–462 is transitioning from the Z to the atoll phase.

ACKNOWLEDGEMENTS

The authors wish to thank Federico García and Kevin Alabarta for useful discussions that helped develop the data analysis methods used in this paper. They also thank the referee for constructive comments that helped improve the manuscript. This research has made use of data and software provided by the High Energy Astrophysics Science Archive Research Center (HEASARC), which is a service of the Astrophysics Science Division at NASA/GSFC.
