

A Preliminary Direct Measurement of the Parity-Violating Coupling of the Z^0 to Strange Quarks, A_s^*

The SLD Collaboration**

Stanford Linear Accelerator Center

Stanford University, Stanford, CA 94309

ABSTRACT

We present an updated direct measurement of the parity-violating coupling of the Z^0 to strange quarks, A_s , derived from the full SLD data sample of approximately 550,000 hadronic decays of Z^0 bosons produced with a polarized electron beam and recorded by the SLD experiment at SLAC between 1993 and 1998. $Z^0 \rightarrow s\bar{s}$ events are tagged by the presence in each event hemisphere of a high-momentum $K^\pm$, K_s or $\Lambda^0/\bar{\Lambda}^0$ identified using the Cherenkov Ring Imaging Detector and/or a mass tag. The CCD vertex detector is used to suppress the background from heavy-flavor events. The strangeness of the tagged particle is used to sign the event thrust axis in the direction of the initial s quark. The coupling A_s is obtained directly from a measurement of the left-right-forward-backward production asymmetry in polar angle of the tagged s quark. The background from $u\bar{u}$ and $d\bar{d}$ events is measured from the data, as is the analyzing power of the method for $s\bar{s}$ events. We measure:

$$A_s = 0.85 \pm 0.06(stat.) \pm 0.07(syst.)(preliminary).$$

1. Introduction

Measurements of the fermion production asymmetries in the process $e^+e^- \rightarrow Z^0 \rightarrow f\bar{f}$ provide information on the extent of parity violation in the coupling of the Z^0 boson to fermions of type f . At Born level, the differential production cross section can be expressed in terms of $x = \cos \theta$, where θ is the polar angle of the final state fermion f with respect to the electron beam direction:

$$\sigma^f(x) = \frac{d\sigma^f}{dx} \propto (1 - A_e P_e)(1 + x^2) + 2A_f(A_e - P_e)x, \quad (1)$$

where P_e is the longitudinal polarization of the electron beam, the positron beam is assumed unpolarized, and the coupling parameters $A_f = 2v_f a_f / (v_f^2 + a_f^2)$ are defined in terms of the vector (v_f) and axial-vector (a_f) couplings of the Z^0 to fermion f . The Standard Model (SM) predictions for the values of the coupling parameters, assuming $\sin^2 \theta_W = 0.23$, are $A_e = A_\mu = A_\tau \simeq 0.16$, $A_u = A_c = A_t \simeq 0.67$ and $A_d = A_s = A_b \simeq 0.94$.

If one measures the polar angle distribution for a given final state $f\bar{f}$, one can derive the forward-backward production asymmetry:

$$A_{FB}^f(x) = \frac{\sigma^f(x) - \sigma^f(-x)}{\sigma^f(x) + \sigma^f(-x)} = 2A_f \frac{A_e - P_e}{1 - A_e P_e} \frac{x}{1 + x^2} \quad (2)$$

which depends on both the initial and final state coupling parameters as well as on the beam polarization. For zero polarization, one measures the product of couplings $A_e A_f$, which has a rather small value since $A_e \simeq 0.16$.

If one measures the distributions in equal luminosity samples taken with negative (L) and positive (R) beam polarization of magnitude P_e , then one can derive the left-right-forward-backward asymmetry:

$$\tilde{A}_{FB}^f(x) = \frac{(\sigma_L^f(x) + \sigma_R^f(-x)) - (\sigma_R^f(x) + \sigma_L^f(-x))}{(\sigma_L^f(x) + \sigma_R^f(-x)) + (\sigma_R^f(x) + \sigma_L^f(-x))} = 2|P_e|A_f \frac{x}{1 + x^2} \quad (3)$$

which is insensitive to the initial state coupling.

It is important to measure as many of these coupling parameters as possible, in order to test the SM ansatz of lepton, up-quark and down-quark universality, respectively.

A number of previous measurements have been made by experiments at LEP and SLC of A_e, A_μ, A_τ, A_c and A_b [1]. The leptonic final states are identified easily by their low track multiplicities and identification of the stable leptons. The $c\bar{c}$ final state can be identified by exclusive or partial reconstruction of the leading charmed hadron in a hadronic jet. The $b\bar{b}$ final state can be tagged by the presence of a lepton with high momentum transverse to the jet axis or of a decay vertex displaced from the primary interaction point, indicating the presence of a leading B hadron in the jet. In contrast, very few measurements exist for the light flavor quarks, due to the difficulty of tagging specific light flavors. It has recently been demonstrated experimentally [2] that light flavored jets can be tagged by the presence of a high-momentum ‘leading’ identified particle that has a valence quark of the desired flavor, for example a K^- (K^+) meson could tag an s ($\bar{s}$) jet. However the background from other light flavors (a $\bar{u}$ jet can also produce a leading K^-), decays of B and D hadrons, and non-leading kaons in events of all flavors is large, and neither the signal nor the background has been well measured experimentally.

The DELPHI collaboration has measured [3] the polar angle production asymmetries of $K^\pm$ mesons in the momentum range $10 < p < 18$ GeV/c, $\Lambda^0/\bar{\Lambda}^0$ baryons in the momentum range $11.41 < p < 22.82$ GeV/c and neutral hadronic calorimeter clusters with $E > 15$ GeV, from which they have measured $A_{FB}^s = 0.131 \pm 0.035(stat.) \pm 0.013(syst.)$ and $A_{FB}^{d,s} = 0.112 \pm 0.031(stat.) \pm 0.054(syst.)$, respectively, where $A_{FB}^{d,s}$ denotes a measurement assuming $A_{FB}^d = A_{FB}^s$. However the extraction of the coupling parameters from the measured production asymmetries is model dependent. The OPAL collaboration has measured [4] the production asymmetries of a number of identified particle species with $x_p = 2p/E_{cm} \geq 0.5$, where E_{cm} denotes the center-of-mass energy in the event, and has determined most of the background contributions and analyzing powers from double-tagged events in the data. This eliminates most of the model dependence, but results in limited statistical precision, yielding $A_{FB}^u = 0.040 \pm 0.067(stat.) \pm 0.028(syst.)$, $A_{FB}^{d,s} = 0.068 \pm 0.035(stat.) \pm 0.011(syst.)$.

In this paper we present a measurement of the coupling parameter for strange quarks, A_s , using the sample of 550,000 hadronic Z^0 decays recorded by the SLD experiment at the SLAC Linear Collider between 1993 and 1998, with an average electron beam polarization of 73%. Hemispheres are tagged as s ($\bar{s}$) by the presence of a K^- (K^+) meson identified by the Cherenkov Ring Imaging Detector (CRID) or a Λ^0 ($\bar{\Lambda}^0$) hyperon tagged using a combination of flight distance and CRID information. The background from heavy flavor events ($c\bar{c}$ and $b\bar{b}$) was suppressed by using B and D hadron lifetime information, allowing the use of relatively low-momentum identified kaons to tag s or $\bar{s}$ jets. The background from the other light flavors ($u\bar{u}$ and $d\bar{d}$) was suppressed by the additional requirement of a high-momentum identified strange particle in the opposite hemisphere of the event. This analysis is discussed in section 3. The coupling parameter was extracted from a simultaneous unbinned maximum likelihood fit to the polar angle distributions measured with left- and right-handed electron beams, as discussed in section 4; this is a direct measurement, i.e. it is insensitive to the initial state coupling, A_e . The analyzing power of the tags for true $s\bar{s}$ events, as well as the relative contribution of $u\bar{u} + d\bar{d}$ events, were determined from the data as described in section 5. This procedure removes much of the model dependence.

2. Apparatus and Hadronic Event Selection

A general description of the SLD can be found elsewhere [5]. The trigger and initial selection criteria for hadronic Z^0 decays are described in Ref. [6]. This analysis used charged tracks measured in the Central Drift Chamber (CDC) [7] and Vertex Detector (VXD) [8], and identified using the Cherenkov Ring Imaging Detector (CRID) [9]. Momentum measurement is provided by a uniform axial magnetic field of 0.6T. The CDC and VXD give a momentum resolution of $\sigma_{p_\perp}/p_\perp = 0.01 \oplus 0.0026p_\perp$, where $p_\perp$ is the track momentum transverse to the beam axis in GeV/ c . About 27% of the data were taken with the original vertex detector (VXD2), and the remaining data with the

upgraded vertex detector (VXD3).

In the plane normal to the beamline the centroid of the micron-sized SLC interaction point (IP) was reconstructed from tracks in sets of approximately thirty sequential hadronic Z^0 decays to a precision of $\sigma_{IP} \simeq 7 \mu\text{m}$ for the VXD2 data and $\simeq 4 \mu\text{m}$ for the VXD3 data. Including the uncertainty on the IP position, the resolution on the charged track impact parameter (d) projected in the plane perpendicular to the beamline is $\sigma_d = 11 \oplus 70 / (p \sin^{3/2} \theta) \mu\text{m}$ for VXD2 and $\sigma_d = 8 \oplus 29 / (p \sin^{3/2} \theta) \mu\text{m}$ for VXD3, where θ is the track polar angle with respect to the beamline. The CRID comprises two radiator systems which identify charged pions with high efficiency and purity in the momentum range 0.3–35 GeV/c, charged kaons in the ranges 0.75–6 GeV/c and 9–35 GeV/c, and protons in the ranges 0.75–6 GeV/c and 10–46 GeV/c [10]. The event thrust axis [11] was calculated using energy clusters measured in the Liquid Argon Calorimeter [12].

A set of cuts was applied to the data to select well-measured tracks and events well contained within the detector acceptance. Events were required to have the VXD and the CDC operational, a minimum of 3 charged tracks with at least 2 VXD hits each, at least 7 charged tracks with $p_\perp > 0.2 \text{ GeV/c}$ and a distance of closest approach within 5 cm along the axis from the measured IP, a thrust axis polar angle w.r.t. the beamline, θ_T , within $|\cos \theta_T| < 0.71$, and a charged visible energy, E_{vis} , of at least 18 GeV, which was calculated from all charged tracks by assigning each the charged pion mass. The efficiency for selecting a well-contained $Z^0 \rightarrow q\bar{q}(g)$ event was estimated to be above 96% independent of quark flavor.

In order to reduce the effects of decays of heavy hadrons, we selected light flavor events ($u\bar{u}$, $d\bar{d}$ and $s\bar{s}$) by requiring at most one high-quality [13] track with transverse impact parameter with respect to the IP of more than 2.5 times its estimated error to be found in each event. The selected sample comprised 244,385 events, with an estimated background contribution of 14.4% from $c\bar{c}$ events, 3.5% from $b\bar{b}$ events, and a non-hadronic background contribution of $0.10 \pm 0.05\%$, dominated by $Z^0 \rightarrow \tau^+ \tau^-$

events.

For the purpose of estimating the efficiency and purity of the event flavor tagging and the particle identification, we made use of a detailed Monte Carlo (MC) simulation of the detector. The JETSET 7.4 [14] event generator was used, with parameter values tuned to hadronic e^+e^- annihilation data [15], combined with a simulation of B -hadron decays tuned [16] to $\Upsilon(4S)$ data and a simulation of the SLD based on GEANT 3.21 [17]. Inclusive distributions of single-particle and event-topology observables in hadronic events were found to be well described by the simulation [6].

3. Selection of $s\bar{s}$ Events

After the event selection described in the previous section, $s\bar{s}$ events are selected by the presence of identified high-momentum $K^\pm$, K_s^0 or $\Lambda^0/\bar{\Lambda}^0$. These particles are likely [2] to contain an initial $s/\bar{s}$ quark, but could also contain an initial u and/or d quark or be from the decay of a D or B hadron. In this analysis the strategy for reducing the model dependence of the result involves hard analysis cuts to suppress the non- $s\bar{s}$ background and enhance the analyzing power of the signal to a level where useful constraints can be obtained from the data.

The first step is the selection of strange particles. The CRID allows $K^\pm$ to be separated from $p/\bar{p}$ and $\pi^\pm$ with high purity for tracks with $p > 9$ GeV/c as described in detail in [10]. For the purpose of identifying $K^\pm$, relatively loose quality cuts are applied. Tracks with poor CRID information or that are likely to have scattered or interacted before exiting the CRID are removed by requiring each track to have a distance of closest approach transverse to the beam axis within 1 mm, and within 5 mm along the axis from the measured IP, to extrapolate through an active region of the CRID gas radiator and through a live CRID TPC. For the remaining tracks log-likelihoods [10, 18] are calculated for the CRID gas radiator for each of the three charged hadron hypotheses $\pi^\pm$, $K^\pm$ and $p/\bar{p}$. A track is tagged as a $K^\pm$ by the gas

system if the log-likelihood for this hypothesis exceeds both of the other log-likelihoods by at least 3 units. Figure 1 shows the momentum distribution of identified $K^\pm$ for our data and Monte Carlo simulation. The data and simulation are in quite good agreement. The average purity of the $K^\pm$ sample was estimated using the simulation to be 91.5%.

The selection of K_s^0 and $\Lambda^0/\bar{\Lambda}^0$ is also described in detail in [10]. Briefly, K_s^0 and $\Lambda^0/\bar{\Lambda}^0$ are reconstructed in the modes $K_s^0 \rightarrow \pi^+\pi^-$ (BR $\approx 69\%$) and $\Lambda^0(\bar{\Lambda}^0) \rightarrow p(\bar{p})\pi^\mp$ (BR $\approx 64\%$) and are identified by their long flight distance, reconstructed mass, and accuracy of pointing back to the primary interaction point.

For the selection of K_s^0 and $\Lambda^0/\bar{\Lambda}^0$, we required a track acceptance of $|\cos\theta| < 0.9$ and at least 30 CDC hits for each track. K_s^0 and $\Lambda^0/\bar{\Lambda}^0$ are required to have $p > 5$ GeV/c and a flight distance with respect to the IP of more than 5 times their estimated uncertainties. Gamma conversions are removed by requiring $m_{ee} > 100$ MeV/ c^2 . The K_s^0 and $\Lambda^0/\bar{\Lambda}^0$ mass cuts mentioned below are parametrized as a function of momentum to take into account the dependence of the $m_{p\pi}$ and $m_{\pi\pi}$ mass resolution, σ , on momentum.

In the case of the $\Lambda^0/\bar{\Lambda}^0$, we next use information from the Cherenkov Ring Imaging Detector to identify the $p/\bar{p}$ candidate if it passes above cuts. We identify the $p/\bar{p}$ candidate if the log-likelihood for this hypothesis exceeds the log-likelihood for the π^+/π^- hypothesis. If CRID information on the $p/\bar{p}$ candidate is not available, we increase the cut on the flight distance with respect to the IP, normalized by its estimated uncertainty, to 10, and require the $m_{\pi\pi}$ of the candidate not to be within 2σ of the nominal K_s^0 mass. Finally, $\Lambda^0/\bar{\Lambda}^0$ are identified by requiring the invariant mass of pairs of tracks, $m_{p\pi}$, to be within 2σ of the nominal $\Lambda^0/\bar{\Lambda}^0$ mass. Figure 1 gives the momentum distribution for the total selected $\Lambda^0/\bar{\Lambda}^0$ sample. The Monte Carlo simulation predicts too many low-momentum $\Lambda^0/\bar{\Lambda}^0$ candidates. We correct this discrepancy in the simulation by applying a momentum-independent correction factor to the number of simulated true $\Lambda^0/\bar{\Lambda}^0$ candidates with $p < 15$ GeV/c; this procedure rejects a total

of 12.5% of the simulated true $\Lambda^0/\bar{\Lambda}^0$ sample within this momentum region but keeps the absolute background level which is seen from $m_{p\pi}$ sidebands to be well simulated. The effect of this correction on the final result will be discussed in section 5. The corrected simulation predicts that the purity of the $\Lambda^0/\bar{\Lambda}^0$ sample is 90.7%.

Pairs of tracks with invariant mass $m_{\pi\pi}$ within 2σ of the nominal K_s^0 mass are identified as K_s^0 . Figure 1 gives the momentum distribution for the K_s^0 sample. The Monte Carlo simulation for the K_s^0 momentum has an excess for low momenta, and similar to the case in the $\Lambda^0/\bar{\Lambda}^0$ sample, we correct this discrepancy in the simulation by applying a momentum-independent correction factor to the number of simulated true K_s^0 candidates with $p < 10$ GeV/c; this procedure rejects a total of 6.9% of the simulated true K_s^0 sample within this momentum region but keeps the absolute background level which is seen from $m_{\pi\pi}$ sidebands to be well simulated. The effect of this correction on the final result will be discussed in section 5. The corrected simulation predicts that the purity of the K_s^0 sample is 90.6%.

These strange particles are then used to tag s and $\bar{s}$ jets as follows. Each event is divided into two hemispheres by a plane perpendicular to the thrust axis. We require each of the two hemispheres to contain at least one identified strange particle ($K^\pm$, K_s^0 or $\Lambda^0/\bar{\Lambda}^0$); for hemispheres with multiple strange particles we only consider the one with the highest momentum. We require at least one of the two hemispheres to have definite strangeness (i.e. to contain a $K^\pm$ or $\Lambda^0/\bar{\Lambda}^0$). In events with two hemispheres of definite strangeness, the two hemispheres are required to have opposite strangeness (e.g. K^+K^-). This procedure increases the $s\bar{s}$ purity substantially compared with a single tag; thus, for these events, the model dependence of the measurement (section 4) is reduced. Table 1 summarizes the composition of the selected event sample for data and simulation for each of the 5 tagging modes used. The number of events for each mode shown is in good agreement with the Monte Carlo prediction. The $s\bar{s}$ purity and $s\bar{s}$ analyzing power were estimated from the data as discussed below.

The $K^\pm K^\mp$ mode and the $K^\pm K_s^0$ mode dominate the sample and the $K^\pm K^\mp$ mode

Table 1: Summary of the selected event sample for 5 modes in data and simulation.

Mode	# Data Events	MC prediction	$s\bar{s}$ purity	$s\bar{s}$ analyzing power
K^+K^-	1290	1312	0.73	0.95
$K^+\Lambda^0, K^-\bar{\Lambda}^0$	218	213	0.65	0.89
$\Lambda^0\bar{\Lambda}^0$	17	14	0.52	0.60
$K^\pm K_s^0$	1580	1614	0.61	0.70
$\Lambda^0 K_s^0, \bar{\Lambda}^0 K_s^0$	189	194	0.50	0.35
Total:	3294	3347	0.65	0.81

has the highest $s\bar{s}$ purity. The combined $s\bar{s}$ purity of all modes is 65%, and the predicted background in the selected event sample consists of 9% $u\bar{u}$, 9% $d\bar{d}$, 16% $c\bar{c}$, and 1% $b\bar{b}$ events.

The analyzing power is defined as:

$$a_s = \frac{N_s^{right} - N_s^{wrong}}{N_s^{right} + N_s^{wrong}} \quad (4)$$

where $N_s^{right}(N_s^{wrong})$ denotes the number of $s\bar{s}$ events in which a particle of negative strangeness is found in the true $s(\bar{s})$ hemisphere. The average analyzing power for all modes is predicted by the simulation to be 0.81. The $K^\pm K^\mp$ mode has a substantially higher analyzing power than the other modes.

The initial s quark direction is approximated by the thrust axis, $\hat{t}$ of the event, signed to point in the direction of negative strangeness:

$$x = \cos\theta_s = S \frac{\vec{p} \cdot \hat{t}}{|\vec{p} \cdot \hat{t}|} \hat{t}_z, \quad (5)$$

where S and $\vec{p}$ denote the strangeness and the momentum of the tagging particle.

Figure 2 shows the polar angle distributions, for all modes combined, of the tagged strange quark, for left-handed and right-handed electron beams. The expected pro-

duction asymmetries, of opposite sign for the left-handed and the right-handed beams, are clearly visible.

4. Extraction of A_s

A_s is extracted from these distributions by an unbinned maximum likelihood fit. The likelihood function is given by:

$$L = \prod_{k=1}^{N_{data}} \{(1 - A_e P_e)(1 + x_k^2) + 2(A_e - P_e) \sum_f (N_f [1 + \delta] a_f A_f x_k)\}. \quad (6)$$

Here, $N_f = N_{events} R_f \epsilon_f$ denotes the number of events in the sample of flavor f ($f = u, d, s, c, b$) in terms of the number of selected hadronic events N_{events} , $R_f = \Gamma(Z^0 \rightarrow f\bar{f})/\Gamma(Z^0 \rightarrow \text{hadrons})$ and the tagging efficiencies ϵ_f ; $\delta = -0.013$ corrects for the effects of hard gluon radiation [19]; a_f denotes the analyzing power for tagging the f rather than the $\bar{f}$ direction; and A_f is the coupling parameter for flavor f . The parameters ϵ_c , ϵ_b , and a_c , a_b for the heavy flavors are taken from the Monte Carlo simulation [16] since a number of independent measurements lead us to believe these parameters to be reliable within well defined uncertainties. The world average experimental measurements of the parameters A_c , A_b , R_c , R_b [1] were used. The corresponding systematic uncertainties are small and are discussed below.

For the light flavors, the relevant parameters in the fitting function are derived where possible from the data. The total number of light flavor events, N_{uds} , is determined by subtracting the number of heavy flavor events (obtained from the simulation) from the entire event sample. The values for the ratio N_{ud}/N_s and the $s\bar{s}$ analyzing power, a_s , depend on the tagging mode as shown in Table 1. As discussed in the next section, the ratio N_{ud}/N_s and the $s\bar{s}$ analyzing power, a_s , for each mode are determined from the simulation and are constrained using the data. The $(u\bar{u} + d\bar{d})$ analyzing power, a_{ud} , for each mode is estimated to be $\pm a_s/2$ (minus sign for K^+K^- , $K^\pm K_s^0$, and $K^+\Lambda^0/K^-\bar{\Lambda}^0$ modes; plus sign for $\Lambda^0 K_s^0/\bar{\Lambda}^0 K_s^0$ and $\Lambda^0 \bar{\Lambda}^0$ modes; section 5). The coupling parameters

A_u and A_d are set to the Standard Model values.

The fit quality of the unbinned maximum likelihood fit to the polar angle distributions, shown in Figure 2, is good with a χ^2 of 25.0 for 28 bins. Also included are our estimates of non- $s\bar{s}$ background. The cross-hatched histograms indicate $c\bar{c} + b\bar{b}$ backgrounds which are seen to show asymmetries of the same sign and similar magnitude to the total distribution. The hatched histograms indicate $u\bar{u} + d\bar{d}$ backgrounds showing asymmetries of the opposite sign and magnitude to the total distribution. The A_s value extracted from the fit is $A_s = 0.85 \pm 0.06(stat.)$.

5. Systematic Uncertainties and Checks

The understanding of the parameters used as inputs to the fitting function and of their uncertainties is crucial to this analysis. The characteristics of heavy flavor events relevant to this analysis have been measured experimentally, and our simulation [14, 15, 17] has been tuned [16] to reproduce these results. The effect of uncertainties in the values of R_c , R_b , A_c and A_b were evaluated by varying those parameters by the uncertainties on their world average values [1]. Uncertainties in other measured quantities such as the D and B hadron fragmentation functions, the number of K^- and K^+ mesons produced per D or B hadron decay, as well as a number of other quantities [6] were taken into account by varying each quantity in turn by plus and minus the error on its world average value. In each case the simulated events were weighted to approximate a distribution generated with the parameter value in question, the Monte Carlo predictions for N_{cb} and a_{cb} rederived, a new fit performed, and the difference between the A_s value extracted and the central value taken as a systematic error.

The sum in quadrature of these uncertainties was taken as the systematic error due to heavy flavor modelling and is listed in Table 2. This is a relatively small contribution to the total systematic error. Other small contributions to the systematic error include

those from the 0.6% uncertainty in the correction for the effect of hard gluon radiation, and the 0.8% uncertainty in the beam polarization.

For the light flavors, there are few experimental constraints on the relevant input parameters. Qualitative features such as leading particle production [2], short range rapidity correlations between high-momentum KK and baryon-antibaryon pairs [20] and long-range correlations between several particle species [20] have been observed experimentally, but these results are not sufficient to quantify the analyzing power of the strange-particle tag or the $u\bar{u}$ and $d\bar{d}$ background. Our Monte Carlo simulation provides a reasonable description of the above observations, and we have used our data to constrain the relevant input parameters in the context of our Monte Carlo model.

For the analyzing power in $s\bar{s}$ events, we note that there are only two ways to mis-tag an s jet as an $\bar{s}$ jet: either the jet must contain a true K^+ or $\bar{\Lambda}^0$ that satisfies our cuts, or we must mis-identify a π^+ or p as a K^+ or reconstruct a fake $\bar{\Lambda}^0$. The Monte Carlo simulation predicts that the fraction of events with a mis-identified particle is negligible in tagged $s\bar{s}$ events, since the majority of high-momentum tracks in these events are kaons, and the relative V^0 fake rate is low. We have measured our mis-identification rates in the data [10], and they contribute less than 0.2% to the wrong sign fraction, so we neglect this source of systematic uncertainty.

If a non-leading high-momentum K^+ is produced in an s jet, then there must be an associated strange particle in the jet, which will also tend to have high momentum. Including the leading strange particle, such a jet will contain one antistrange and two strange particles, all with relatively high momentum. We can therefore investigate the rate of production of these wrong-sign kaons by studying events in which we find three identified $K^\pm$ and/or K_s^0 in the same hemisphere. Such an event sample is expected to be fairly pure in $s/\bar{s}$, since a $u/\bar{u}$ or $d/\bar{d}$ jet would have to contain either four strange particles or two strange particles and one mis-identified particle in order to be selected. In our data we found 68 hemispheres containing three identified $K^\pm$ and/or K_s^0 , compared with a Monte Carlo prediction of 73. We subtracted the simulated non- s

jet background of 27 events to yield a measured number of 41 ± 9 jets with 3 kaons, providing a 20% constraint on the number of $s\bar{s}$ events that *could* have the wrong sign. Since the Monte Carlo prediction is consistent with the data, we used the simulated a_s for each mode (see Table 1) as our central value for the analyzing power in $s\bar{s}$ events. This constraint is not entirely model-independent, since we are relying on the model to predict the fraction of these jets in which all three kaons pass our momentum cuts, as well as the fraction in which the wrong-sign kaon is chosen as the tagging particle rather than either of the right-sign kaons. We also assume equal production of charged versus neutral kaons (as in the Monte Carlo simulation); thus, this procedure delivers a simultaneous calibration of the analyzing power in $s\bar{s}$ events for the K^+K^- and $K^\pm K_s^0$ modes. However, we trust the Monte Carlo simulation for the modes involving $\Lambda^0/\bar{\Lambda}^0$. Therefore, we conservatively applied the 20% uncertainty to the wrong-sign fraction of each tagging mode, resulting in a 3% uncertainty on A_s , as shown in Table 2. We also counted hemispheres containing a K^+K^+ or K^-K^- pair, obtaining a consistent but less precise constraint.

The relative $u\bar{u} + d\bar{d}$ background level N_{ud}/N_s was constrained from the data by exploiting the fact that an even number of strange particles must be produced in a u/d jet, and that they appear in strange-antistrange pairs that have similar momenta. We counted 1262 hemispheres in the data containing an identified K^+K^- pair and 983 hemispheres containing an identified $K^\pm K^0$ pair. The respective Monte Carlo predictions of 1215 and 1005 are consistent. After subtracting the predicted non- u/d jet backgrounds, these two checks yielded 9% and 8% constraints, respectively, on the $u\bar{u} + d\bar{d}$ background. We also counted events in the data that were tagged by kaons of the same sign in both hemispheres. The Monte Carlo prediction is consistent, but the constraint obtained is less precise. Again, we have used the Monte Carlo central value for each tagging mode and, since the constraints are not completely model-independent, we have used only the most precise one to estimate the systematic uncertainty.

The above checks are also sensitive to the analyzing power of $u\bar{u} + d\bar{d}$ events, a_{ud} .

beam polarization	data	$(73.4 \pm 0.8)\%$	0.011
a_s	MC constrained by 3 K jets in data	$\pm 20\%$ on wrong sign fraction	0.034
a_{ud}	$a_{ud} = \pm a_s/2$	$\pm 57.7\%$	0.057
A_{ud}	Standard Model	—	—
N_{ud}/N_s	MC constrained by 2 K jets in data	$\pm 8.4\%$	0.028
MC statistics			0.019
Total:			0.077

However, with the present event statistics we cannot obtain a tight constraint on this quantity. We therefore assume that a_{ud} must be negative (positive) for the K^+K^- , $K^\pm K_s^0$, and $K^+\Lambda^0/K^-\bar{\Lambda}^0$ modes ($\Lambda^0 K_s^0/\bar{\Lambda}^0 K_s^0$ and $\Lambda^0 \bar{\Lambda}^0$ modes), since u and d jets must produce a leading K^+ (Λ^0) rather than K^- ($\bar{\Lambda}^0$), and that the modulus of a_{ud} must be less than that of a_s , since there is always a companion particle of opposite strangeness in a u or d jet that will tend to dilute the analyzing power. For all 5 tagging modes, we take these as hard limits, $0 < |a_{ud}| < a_s$, use the middle of the range for our central value and assign an uncertainty equal to the range divided by $\sqrt{12}$. The shift in central value of A_s due to this estimation of a_{ud} , as compared to the simulated values for a_{ud} , was found to be negligible.

The effects on the central value of A_s due to the corrections (section 3) of the Monte

Carlo K_s^0 and $\Lambda^0/\bar{\Lambda}^0$ momentum distributions were studied. It was determined that the changes in the $s\bar{s}$ purity and the analyzing power in $s\bar{s}$ events were small. The change in the central value of A_s when these corrections were removed was smaller than any of the contributions listed in Table 2 and we considered it to be negligible. The individual systematic errors were added in quadrature to yield a total systematic error of $\delta A_s/A_s = 0.077$, i.e. $\delta A_s = 0.07$.

6. Summary and Conclusion

We have presented a preliminary direct measurement of the parity violating coupling of the Z^0 to strange quarks, A_s , derived from the sample of approximately 550,000 hadronic decays of Z^0 bosons produced with a polarized electron beam and recorded by the SLD experiment at SLAC between 1993 and 1998. The precision CCD vertex detector allows the suppression of the heavy flavor background, and the Cherenkov Ring Imaging Detector is crucial in the tagging of high-momentum $K^\pm$ and helps improve the $\Lambda^0/\bar{\Lambda}^0$ purity. The coupling A_s is obtained directly from a measurement of the left-right-forward-backward production asymmetry in polar angle of the tagged s quark. The background from $u\bar{u}$ and $d\bar{d}$ events is measured from the data, as is the analyzing power of the method for $s\bar{s}$ events.

An unbinned maximum likelihood fit is used to obtain the result:

$$A_s = 0.85 \pm 0.06(stat.) \pm 0.07(syst.)(preliminary). \quad (7)$$

This result is consistent with the Standard Model expectation for A_s . Our measurement can be used to test the universality of the coupling constants by comparing it with the world average value for A_b [1]. The two measurements are consistent.

In order to compare with previous measurements of A_{FB}^s and $A_{FB}^{d,s}$ (see section 1), we must assume a value of A_e . Using $A_e = 0.1499$ [1] and neglecting the small uncertainty on A_e , the DELPHI measurements translate into $A_s = 1.165 \pm 0.311(stat.) \pm$

$0.116(\textit{syst.})$ and $A_{d,s} = 0.996 \pm 0.276(\textit{stat.}) \pm 0.480(\textit{syst.})$. Similarly, the OPAL measurement yields $A_{d,s} = 0.605 \pm 0.311(\textit{stat.}) \pm 0.098(\textit{syst.})$. Our measurement is consistent with these and represents a substantial improvement in precision.

Acknowledgements

We thank the personnel of the SLAC accelerator department and the technical staffs of our collaborating institutions for their outstanding efforts on our behalf.

Figure 1: Momentum distributions for selected (a) $K^\pm$, (b) $\Lambda^0/\bar{\Lambda}^0$ and (c) K_s^0 candidates in the data (dots). Also shown is the Monte Carlo simulation (histogram). The Monte Carlo distributions for $\Lambda^0/\bar{\Lambda}^0$ candidates and K_s^0 candidates were later corrected, as described in the text.

Figure 2: Polar angle distributions of the tagged strange quark, for negative (left) and positive (right) beam polarization. The dots show data, and our estimates of the non- $s\bar{s}$ backgrounds are indicated by the hatched histograms.
