Neutrino Phenomenology of Very Low-Energy Seesaws

André de Gouvêa, James Jenkins, and Nirmala Vasudevan
Northwestern University, Department of Physics & Astronomy, 2145 Sheridan Road, Evanston, IL 60208, USA

The Standard Model augmented by the presence of gauge-singlet right-handed neutrinos proves to be an ideal scenario for accommodating nonzero neutrino masses. Among the new parameters of this new Standard Model are right-handed neutrino Majorana masses. Theoretical prejudice points to much larger than the electroweak scale, but it has recently been emphasized that all of these values are technically natural and should be explored. Indeed, $M \sim 10 \text{ eV}$ can accommodate an elegant oscillation solution to the LSND anomaly, while other values lead to several observable consequences. We consider the phenomenology of low-energy ($M \sim 1 \text{ keV}$) seesaw scenarios. By exploring such a framework with right-handed neutrinos, we can consistently explain oscillation data, including those from LSND, while partially addressing several astrophysical puzzles, including anomalously small nonthermal neutrino fluxes in supernovae, and the existence of warm dark matter. Furthermore, low-energy seesaws regardless of their relation to the LSND anomaly can also be tested by future tritium beta-decay experiments, neutrinoless double-beta decay searches, and other observables. We estimate the sensitivity of such probes to $M$.

I. INTRODUCTION

Neutrinos have provided our first glimpse into physics beyond the Standard Model of elementary particles (SM). Neutrino oscillation experiments have given us unambiguous evidence that the three active neutrinos have mass and mix (see [1] for recent reviews of neutrino theory and phenomenology). As most important discoveries, the results of these experiments have raised more questions than they answered. Even from our limited knowledge of the neutrino, it is clear that their properties, including sub-eV masses and large mixing, are quite different from their charged fermion counterparts. The true explanation of this puzzling behavior likely rests on the fact that neutrinos are the only fundamental fermions, but the exact reason behind this is still open to speculation. Neutrino masses, as deduced from oscillation experiments, hint at the existence of right-handed neutrino states, lepton number violation, new sources of CP violation, as well as a new energy scale.

The seesaw mechanism [2] is an appealing way to generate the observed neutrino mass and lepton mixing matrix. The idea is simple. Add an arbitrary number of singlet fermion states to the SM matter content. The triviality of their quantum numbers allows them to have Majorana masses of 1 MeV, as well as coupling to the SU(2) lepton and Higgs doublets. The latter vertices become Dirac mass terms if their mass is of order the charged fermion mass, while the Majorana masses are at very high energy scale, $M \sim 100 \text{ GeV}$. If this is indeed the case, the resulting propagating neutrino degrees of freedom separate into two quasi-decoupled groups: mostly active states with very small Majorana mass $M^2 \sim M^{10^2}$ suppressed by the new physics scale, and mostly sterile states with very large mass $M$. In this scenario, the mostly right-handed states are not directly observable. Indeed, it is possible that such a high-energy seesaw is realized in Nature, its only observable consequence is that the mostly active neutrinos have mass and mix.

Of course, there is no direct evidence that $M$ (which we refer to as the seesaw scale) is large. Large $M$ values are attractive for several reasons, including the fact that one may relate $M$ to the grand unified scale. On the other hand, small $M$ values are technically natural, given that when $M$ vanishes the global symmetry structure of the Lagrangian is enhanced: $U(1)_{B-L}$ is a symmetry of the Lagrangian if $M = 0$, so that $M$ is often referred to as the lepton number breaking scale. This point was recently emphasized in [3]. Recent analyses have also revealed that there are several low-energy choices for the seesaw energy scale that allow one to address outstanding problems in particle physics and astrophysics. The main reason for this is that, unlike the high-energy seesaw, in a low-energy seesaw the mostly right-handed states do not decouple but remain accessible sterile neutrinos.

The data reported by the LSND short baseline neutrino oscillation experiment [4] can be explained by postulating the existence of light ($m < 10 \text{ eV}$) sterile neutrino states. This result is currently being tested by the Ember II and Hōkūle'a experiments. And, if one sees nonthermal neutrino fluxes in supernovae, for example, the seesaw right-handed neutrinos can play the role of the LSND sterile neutrinos. There is also evidence for sterile neutrinos at other energy scales: eV sterile neutrinos add a heavy element nucleosynthesis in supernovae, keV sterile neutrinos can help explain the peculiar velocity of pulsars, and a nonthermal warm dark matter candidate in the past several million years, it has been shown that the sterile right-handed neutrinos may play the role of all three astrophysically/originologically...
inspired sterile neutrinos [7,8].

In this paper, we consider the phenomenology of low-energy (M ~ 1 keV) seesaw scenarios, extending the analysis performed in the previous study [3]. In Sec. II, we review the generation of neutrino mass via the seesaw mechanism and apply it to relatively light-handed neutrino states. We pay special attention to the most general active-sterile seesaw mixing matrix, whose parameters are the main object of our study. In Sec. III, we review the several different evidence cases for sterile neutrinos, and discuss whether there can be \( t \) the low-energy seesaw. We concentrate on exploring solutions that can accommodate the same time the LSND anomaly and the astrophysical processes outlined above, but also discuss different combinations of the seesaw parameters capable of explaining only the astrophysics-related observables. In Sec. IV, we examine the experimental probes that can be used to explore low-energy seesaw models regardless of their relationship to the LSND anomaly, pulsar kicks, and warm dark matter. We concentrate on the prospects of current/future tritium beta-decay and neutrinoless double-beta decay experiments. We conclude in Sec. V by summarizing our results, commenting on the plausibility of this scenario, and offering a general outlook for the future.

II. THE SEESAW MECHANISM AND ELECTRON VOLT NEUTRINO MASSES: PRELIMINARIES

In order to account for nonzero neutrino masses, we add to the SM particle content three SU(3), SU(2), U(1) gauge singlet fermion states \( N_i \), conventionally referred to as right-handed neutrinos, while sterile under SM gauge interactions, right-handed neutrinos may still be charged under new, currently unknown gauge transformations. Such interactions, if at all present, are neglected in our analysis.

The most general renormalizable Lagrangian consistent with SM gauge invariance is

\[
L = L_{\text{old}} + \sum_{i} \bar{H} N_i \nu_i^c \nu_i + \text{H.c.}
\]

where \( L_{\text{old}} \) is the traditional SM Lagrangian, \( H \) is the Higgs weak doublet, \( \nu_i \), \( i = e, \mu, \tau \), are lepton weak doublets, \( \nu_i \), \( i = e, \mu, \tau \), are neutrino Yukawa couplings, and \( M_1 \) are Majorana masses for the \( N_i \). We choose, without loss of generality, the Majorana mass matrix \( M_R \) to be diagonal and its eigenvalues \( M_i \) to be real and positive. We also choose the charged lepton Yukawa interactions and the charged weak current interactions diagonal so that all physical mass eigenstates are contained in the neutrino sector.

After electroweak symmetry breaking (when \( H \) develops a vacuum expectation value \( v \)), \( L \) will describe, aside from all other SM degrees of freedom, six neutral massless weak electroweak fermions | six neutrinos. The resulting mass terms can be expressed as:

\[
L = \frac{1}{2} \bar{v} \nu \nu^c M_R \nu^c + \text{H.c.}
\]

where \( v \), \( \nu \), and \( \nu^c \) are vectors of the three active neutrinos \( (\nu_e, \nu_{\mu}, \nu_{\tau}) \) and the three right-handed, sterile states, respectively. Each entry in the symmetric mass matrix of Eq. (II.2) is itself a 3 \( \times \) 3 matrix of mass parameters. Diagonalization of the mass matrix yields eigenstates with Majorana masses that mix the active/sterile states, related via the standard lepton mixing matrix \( V \), and the active/sterile states. The physical neutrinos are thus linear combinations of all active and sterile states. Throughout, we will work in the \( \text{seesaw limit} \), denoted by \( M_R \). In this case, there are three mostly active light neutrinos and three mostly sterile heavy neutrinos where 'mostly' is determined by the induced mixing parameters.

In the seesaw limit, the diagonalization is simple. We have:

\[
0 = 1 \quad 0 \quad m \quad 0 \quad V^T \quad 0 \quad 1 \quad + \text{O}(2);
\]

where \( m \) is the diagonal matrix of light neutrino masses and \( V \) is a matrix of active/sterile mixing angles found from the relations:

\[
M_R = v ;
\]

\[
M_R^T = V m V^T ;
\]

The elements of \( M_R \) are small \( \text{O}(v^\text{2}) \), and the standard seesaw relation \( (V m V^T = M_R^{-1}) \) is easily obtained by combining Eqs. (II.4) and Eqs. (II.5). On the other hand, using Eq. (II.5), we can relate the mixing parameters in
to the active (active mixing angles contained in $V$ and the neutrino mass eigenvalues. In the case of observably light sterile neutrino masses, as considered in our analysis, this equation is very useful, as it places testable constraints on observable quantities. The general solution (rst discussed in detail in [6]) of Eq. (II.5) is

$$V m = M R_{1=2}$$

(II.6)

where $O$ is an orthogonal matrix parametrized by three mixing angles $12, 13, 23$. Physically, the mixing matrix $O$ is a consequence of our freedom to choose the form of $M_R$. An illustrative example is found by considering the masses ordering of $M_R$ in its diagonal form. The reordered mixing matrix $M_R (m_1 < m_2)$ is equivalent to a $-2$ rotation in the $i,j$ plane and therefore represents the same physics as the original mixing, as it should. In other words, $O M_R O^T$ is the physically relevant object, as opposed to $O$ and $M_R$ separately. This object, when constrained to be real, has six free parameters that we shall refer to as \(\text{heavy} \) parameters. \(12, 13, 23 \text{, } M_1, M_2, M_3 \).

Using Eq. (II.6), the $6 \times 6$ unitary neutrino mixing matrix is

$$U = V_{\text{mix}}$$

(II.7)

Note that, up to $O (2)$ corrections, $V$ is unitary. $U$ is entirely described in terms of the three light mixing angles, six mass eigenvalues, and three angles $\theta_i$. Any combinations of these have been measured or constrained via oscillation searches, cosmology, and astrophysics. In particular, the two active neutrino mass-squared differences and mixing angles have been measured $\theta_1, \theta_2, \theta_3$, thus leaving free the six heavy parameters and the absolute scale of active neutrino masses. With $U$, the corresponding neutrino mass values and the SM couplings, we can calculate all observable quantities and compare them with data.

It is natural to wonder how well the seesaw approximation holds once one starts to deal with $M_R$ values around 1 eV. From Eq. (II.5), it is clear that one can choose the expansion parameter $m = M_R$. In all scenarios considered here, $m = M_R < 0.5$ (for $M = 1 \text{ eV}$ and $m = 0.3 \text{ eV}$). In the worst case scenario, therefore, the second order corrections are 55% of the leading order term, while second order corrections are near 30%. Corrections to most observables of interest are much smaller than this because they are suppressed by larger right-handed neutrino masses. The $-$1st non-trivial correction to Eq. (II.5) occurs at second order and we note that, for the ambitions of this paper, all approximations are under control. This simple argument has been veriﬁed numerically for the most worrisome cases.

Before concluding this section, we wish to add that operators that lead, after electroweak symmetry breaking, to Majorana masses for the left-handed neutrino states ($M_L$) are also allowed if one introduces $SU(2)$. Higgs boson triplets or non-renormalizable operators to the SM Lagrangian. While we neglect these 'active' Majorana masses, we caution the reader that the existence of such terms would alter our results signiﬁcantly. In particular, assuming the seesaw approximation holds, Eq. (II.5) would read

$$V m V^T + M_R = M_L$$

(II.8)

which leads to a relationship between $m$, $M_R$, and $M_L$ different from Eq. (II.6). If this were the case, for example, it would no longer be true that the largest value (in absolute value) is constrained to be smaller than $(m_{\text{max}} M_{\text{max}})^{1/2}$, where $m_{\text{max}}$ is the largest element of $m$, while $M_{\text{max}}$ is the smallest element of $M_R$. On the other hand, all objects on the left-hand side of Eq. (II.5) are observables. Hence, in the case of a low-energy seesaw, one expects, in principle, to be able to test whether there are contributions to the neutrino mass matrix that are unrelated to the presence of right-handed neutrinos. By measuring $V, m, M_R$, and $M_L$, one can establish whether $M_L$ is consistent with zero.

III. OSCILLATION PHENOMENOLOGY AND CURRENT EVIDENCE FOR LOW-ENERGY SEESAW

Here we examine a number of experimental and observational anomalies that may be explained by light sterile neutrinos. More speciﬁcally, we explore what these can teach us about the currently unknown parameters of the seesaw Lagrangian, described in detail in Sec. I. In all cases we assume $3 \text{ m ostly active and } 3 \text{ m ostly sterile neutrinos}$ and, most of the time, will concentrate on a $3+2+1$ picture of neutrino mass eigenstates, that is, three mostly active

In general, $O$ is a complex orthogonal matrix. Here, however, we will restrict our analysis to real neutrino mass matrices, unless otherwise noted.

\[ \text{The active neutrino mass hierarchy, normal vs. inverted, is another (discrete) free parameter.} \]
sub-eV neutrinos, two mostly sterile eV neutrinos and one almost completely sterile keV neutrino. The hope is that the heavier state can account for warm dark matter (section \[\text{HEX}\]) or pulsar kicks (Sec. \[\text{HEC}\]), which both require at least one keV neutrino, while the other two mostly sterile states help explain the existing oscillation data where, for all practical purposes, the heaviest neutrino dominates and we are left with an effective 3+1 or 3+2 picture. We remind readers that a third possibility (2+2) is currently ruled out by both solar and atmospheric data \[\text{EX},\text{EI},\text{EJ}\] and will be ignored. 3+1 schemes that address the LSND anomaly are also disfavored by global analysis of short baseline oscillation experiments \[\text{HZ},\text{IK},\text{II},\text{IL}\], and for this reason, we most concentrate on 3+2 ts to the LSND anomaly \[\text{II}\].

Our analysis method is as follows: For each experimental probe considered we perform a \( t^2 \) of the mixing matrix \( U \), given by Eq. \[\text{II}\], and neutrino masses are to the 'data', and extract the region of parameter space that best explains the data. In most cases, we allow the light, mixing angles and mass squared differences to vary within their limits (according to \[\text{II}\])\(^a\), the angles \( \theta \) to vary unconstrained within their physical limits of \( 0 \leq \theta \leq \pi \), and the lightest active neutrino mass eigenvalue \( m_1 \) to vary unconstrained between 0 and 0.05 eV. The quotation marks around 'data' and 'data' are meant to indicate that our methods are crude, in the sense that we are fitting to previously processed experimental data, assuming a diagonal correlation matrix with Gaussian uncertainties. In order to avoid the subtleties involved in such a \( t^2 \) and 'data', we hesitate to mention actual confidence intervals, but are compelled to do so for lack of a better measure of an allowed region. We sometimes present our best fitting parameters along with confidence intervals, but warn the reader to avoid strict interpretations of these numbers. While crude, our methodology of error analysis and fitting provides a very useful instrument for identifying whether (and how) the low-energy seesaw can accomodate a particular combination of data sets.

Before proceeding, it is useful to cement our notation. The neutrino mass matrices will be ordered in ascending order of magnitude from \( m_1 \) to \( m_6 \) in the case of a normal active neutrino mass hierarchy \((m_2^2 > m_1^2 > m_3^2)\), while in the case of an inverted mass hierarchy they are ordered \( m_3 < m_1 < m_2 < m_4 < m_5 < m_6 \) (in this case \( m_2^2 < m_1^2 > m_3^2 \)). The states with mass \( m_1 \) act like 'active', while those with mass \( m_4 \) are 'mostly sterile'. Elements of the mixing matrix are referred to as \( U_{ij} \), where \( i \leq j \); \( \theta_i \), 2\( \theta_2 \), \( \theta_3 \), \( s_i \) are the right-handed neutrino degrees of freedom \( i = 1; 2; 3; 4; 5; 6 \). We also define \( m_i^2 = m_i^2 - m_j^2 \) and will refer to the lightest active neutrino mass as \( m_1 \). In the case of normal (inverted) active neutrino mass hierarchy \( m_1 = m_1 \) \( (m_1 = m_3) \).

### A. Short baseline oscillation constraints

Here we analyze the constraints imposed on the unknown mixing parameters by current neutrino oscillation data. We will assume that all solar, reactor, long-baseline, and atmospheric data are properly treated with active-active oscillations, and that constraints on the seesaw model are provided mostly by short baseline accelerator experiments. It is interesting to note that the inclusion of the angles \( \theta \) introduces enormous freedom into the system. Any one active(sterile) mixing angle contained in \( \theta \) can always be set to zero by an appropriate choice of \( \theta \). In fact, all but three elements may be set to zero simultaneously with only a single non-zero element in each row and column. In this case, these are constrained to be around \( m_i^2 = m_i \) where \( i \) is the column of the non-zero element. This is especially true when the mostly active neutrino mass matrices are quasi-degenerate. An important sum rule of thumb \( b \) states that a given right-handed neutrino mass \( m_i \), the active/sterile mixing angle squared is of order \( m_i \), where \( m_i \) is a typical active neutrino mass. One can always choose parameters so that, for all mass, two values of \( m_i \) are very small. In that case, however, the other \( U_i \) is constrained to saturate the bound \( j \leq i \). \( m_i \).

The most compelling evidence for light sterile neutrinos comes from the short baseline oscillation experiment by the Liquid Scintillator Neutrino Detector (LSND) collaboration at Los Alamos. Using a \( 30 \text{ MeV} \) beam they observed a better than \( 3 \) excess of events above their expected background at their detector some \( 30 \text{ m} \) away from the production point \( \text{E}[\text{I}] \). This evidence of \( \text{E}[\text{I} \to \text{I}] \) oscillation requires a mass-squared difference greater than \( 1 \text{ eV}^2 \), clearly incompatible with the small mass-squared differences observed between the active neutrinos. Several mechanisms, such as CPT violation \[\text{HI},\text{II}\], Lorentz invariance violation \[\text{HE}\], quantum decoherence \[\text{HJ}\], sterile neutrino decay \[\text{HK}\] and, of course, oscillation into sterile neutrinos have been re-proposed to explain this result. Here we concentrate on the last possibility.

In order to take into account all short baseline data we \( t^2 \) our mixing parameters and masses to the results of the \( 3+2 \) performed in \[\text{E}[\text{II}],\text{IL}\], which are summarized in Table \[\text{E}[\text{I}],\text{I}\]. Here we assume that the heaviest, mass-seele state does not participate effectively in LSND oscillations. This is guaranteed to happen if \( m_6 > 10 \text{ eV} \). On the other hand, it would have been rather difficult to construct a \( 2+2 \) neutrino mass hierarchy using the seesaw Lagrangian.

\(^a\) In the case of \( 3+1 \) 'data' (cf. Eqs. \[\text{HEX},\text{HEC}\]), we keep the active neutrino parameters fixed at their best-fit values.
hand, \( j \not\in \{ \ell \} \) are partially constrained by our attempt to accommodate LSND data with seesaw sterile neutrinos, as will become clear in the next subsections.

We find that \( m_1 \), the lightest neutrino mass, is constrained to lie between (0.22 \( \pm \) 0.37) eV, with a "best t" value of 0.29 eV. Thus, the active neutrino mass spectrum is predicted to be quasi-degenerate. A sample 6 × 6 neutrino mixing matrix that fits all data is

\[
U_{3\times2} = \begin{pmatrix}
0 & 0.8301 & 0.5571 & 0.001365 & 0.0193 & 0.09399 & 0.006513 \\
0.0394 & 0.5866 & 0.7072 & 0.2016 & 0.2262 & 0.003363 & 0.000351 \\
0.0393 & 0.5879 & 0.7070 & 0.0170 & 0.0949 & 0.001470 & 0.000031 \\
0.0207 & 0.0951 & 0.0479 & 1 & 0 & 0 & 0 \\
0.0134 & 0.0183 & 0.0928 & 0 & 1 & 0 & 0 \\
0.004963 & 0.00429 & 0.001268 & 0 & 0 & 1
\end{pmatrix} \quad (\text{III.9})
\]

while the associated masses are \( m_1' \) \( m_2' \) \( m_3 = 0.28 \) eV, \( m_4 = 1.0 \) eV, \( m_5 = 4.7 \) eV, and \( m_6 = 6.1 \) keV. Note that the matrix in Eq. (III.9) is only approximately unitary, up to corrections of order 25%. This result agrees qualitatively with those obtained in [3]. The neutrino masses and mixings obtained in this \( t'' \) are depicted in Fig. 1. We will use the results of this \( t'' \) similar to this one throughout the paper.

One can also aim at (currently disfavored) 3 + 1 LSND \( t'' \). In this case, much lower \( m_1 \) values are also allowed, extending well into the hierarchical spectrum range. In this case, all \( m_i \) values above 0.01 eV and 0.03 eV are allowed, assuring an inverted and normal mass hierarchy, respectively. This is to be compared with the results found in [1], where only trivial choices for \( O \) were considered. Examples that \( t'' \) all oscillation data include, for an inverted active mass hierarchy: \( m_1' \) \( m_2' \) \( m_3 = 0.066 \) eV, \( m_4 = 0.043 \) eV, \( m_5 = 0.96 \) eV, \( m_6 = 5 \) keV, and \( m_5 = 10 \) GeV, together with

\[
U_{3\times1}^{\text{inverted}} = \begin{pmatrix}
0 & 0.8305 & 0.5571 & 0 & 0.1359 & 0.00009142 & 0.00002198 \\
0.0393 & 0.5872 & 0.7071 & 0.2046 & 0.00005000 & 0.00001202 & 0.00000154 \\
0.0148 & 0.2218 & 0.0134 & 1 & 0 & 0 & 0 \\
0.0013 & 0.0018 & 0.0025 & 0 & 1 & 0 & 0 \\
0.00002372 & 0.00000409 & 0.00000718 & 0 & 0 & 1
\end{pmatrix} \quad (\text{III.10})
\]

For a normal mass hierarchy, we find that \( m_1 = 0.055 \) eV, \( m_2 = 0.056 \) eV, \( m_3 = 0.0744 \) eV, \( m_4 = 0.96 \) eV, \( m_5 = 5 \) keV, \( m_6 = 10 \) GeV, and

\[
U_{3\times1}^{\text{normal}} = \begin{pmatrix}
0 & 0.8305 & 0.5571 & 0 & 0.1173 & 0.0002100 & 0.00001418 \\
0.0393 & 0.5872 & 0.7071 & 0.2176 & 0.0004625 & 0.00000136 & 0.00001283 \\
0.0502 & 0.1355 & 0.2231 & 1 & 0 & 0 & 0 \\
0.0008214 & 0.002545 & 0.002310 & 0 & 1 & 0 & 0 \\
0.00000222 & 0.00000764 & 0.00000056 & 0 & 0 & 1
\end{pmatrix} \quad (\text{III.11})
\]

\( t'' \) all oscillation data quite well.

Note that a null result from MiniBooNE is bound to place significant limits on the seesaw energy scale. If all right-handed neutrino masses are similar, the effective mixing angle that governs the transition is \( \sin^2 2 \theta_{\text{M inBooNE}} \).

* This is easily accomplished by requiring \( m_5 > 10 \) eV.
Fig. 1: Neutrino mass eigenstate spectrum, along with the flavor composition of each state. This case accommodates all neutrino oscillation data, constraints from r-process nucleosynthesis in supernovae, and may help explain anomalous pulsar kicks (see text for details). While we choose to depict a normal hierarchy for the active neutrino states, an inverted active neutrino mass hierarchy would have yielded exactly the same physics (as far as the observables considered are concerned).

4m^2=\text{M}^2. Hence, a null result at LSND would rule out a seesaw energy scale M lighter than 6 eV, assuming all active neutrino masses are around 0.1 eV [5]. This is if it is sensitive to the lightest neutrino mass m_1 and can be somewhat relaxed (similar to how we obtain a good 3+2 to all neutrino data) by postulating a (m_6) hierarchy of right-handed neutrino masses and by assuming that sterile-electron and sterile-muon neutrino mixing is suppressed with respect to naive expectations for the lightest mostly sterile state(s). For larger values of m_1, M values around 10 eV are already constrained by searches at the NuTeV [21] and NOMAD [22] experiments, and searches at CHORUS [23].

B. Cosmological and Astrophysical Constraints, Warm Dark Matter

Very light sterile neutrinos that are with the active neutrinos are constrained by several cosmological and astrophysical observations. The seesaw right-handed neutrinos are no exception. Given that active-sterile mixing angles sin^2 \theta_{i}m_{i}m_{1} (= e; \ i = 4, 5, 6), it turns out that for standard cosmology, the right-handed neutrinos thermalize with the early universe and all SM particles, as long as the reheating temperature is higher than their Majorana masses. For low seesaw energy scales we are interested in, this is a problem. For the values of M_R under consideration here, thermal right-handed neutrinos easily overclose the universe. Smaller m_1 values (m_1 < 10^5 eV) lead to the possibility that right-handed neutrinos are the dark matter, as recently discussed in the literature [7,8]. We comment on this and other possibilities shortly.

Fig. 2 depicts the region of the \( \mu \epsilon \) plane in which the contribution of the heaviest neutrino \( \nu_e \) to the normalized energy density of the universe, \( \epsilon = \frac{\rho_{\nu_e}}{\rho_{\text{crit}}} \), is larger than 0.3 (dark region). The same constraint roughly applies for all \( \mu \epsilon \) and \( \iota = 4, 5, 6 \). The dashed diagonal lines correspond to \( \mu \epsilon = m = m_1 \), for different values of m_1. All lines lie deep within the dark \( \epsilon > 0.3 \) region.

For smaller values of M_R, the situation is also constrained. For M_R values below tens of eV, therm all sterile neutrinos
follows: constraints on warm dark matter can be translated into a lower bound on the mostly sterile neutrino mass.

![Diagram](image.png)

**FIG. 2:** Adapted from [44]. Cosmological and astrophysical constraints on the $\Omega_{s} \Omega_{\mu}$ plane. In the large dark grey region, the density of a thermal population is $\Omega_{s} > 0.3$, while the light grey 'X-ray' region is disfavored by X-ray observations. The regions labeled 1, 2, 3 are preferred if one is to explain anomalous pulse kicks with active/sterile oscillations inside supernovae. Regions 1 and 3 qualitatively extend inside the $\Omega_{s} > 0.3$ part of the plane as indicated by the horizontal dotted and dash-dotted lines, respectively. The regions 'Too Warm Dark Matter' and 'Too Warm Dark Matter' are meant to represent the region of parameter space where there also qualifies as a good (or bad) warm dark matter candidate. The region above the solid diagonal line is disfavored by the observation of electron (anti)neutrinos from SN1987A. The diagonal dashed lines correspond to $U_{i6}^2 = m_{i}m_{\mu}$, for different values of $m_{i}$. Also shown is our 'best fit' sterile solution for different pulse kick scenarios, assuming the $3+2$ LSND data for the lighter states. The regions one and three best fit values are represented by circles and a star, respectively. See text for details.

One way to avoid the bounds described above (see also, for example, [34]) is to consider that the reheating temperature of the universe is very low, say $T_{r} \approx 5 \text{ MeV}$ [24]. This way, right-handed neutrinos, in spite of their 'large' mixing angles, never reach a thermal equilibrium in the early universe and neither overclose the universe, nor contribute to the amount of hot dark matter. Unless otherwise noted, this is the assumption we make here.

Under these circumstances, it is interesting to consider whether light seesaw right-handed neutrinos still qualify as good warm dark matter. This could happen if their production in the early universe was non-thermal. One concern surrounding warm dark matter is whether it is ruled out by large scale structure surveys. Here, we will not add to this discussion but refer readers to the recent literature on the subject [34]. A brief summary of the situation is as follows: constraints on warm dark matter can be translated into a lower bound on the mostly sterile neutrino mass.

In our best fit solution to the LSND data, the sum of all active neutrino masses violates slightly the constraint obtained in [24]. This problem can be easily evaded if we choose $m_{i}$ values close to the lower end of the 'allowed region'. Other 'non-standard' non-standard cosmology effects [24] are also known to alleviate the hot dark matter bound on neutrino masses.
The lower bound has been computed by different groups, and lies somewhere between 3 and 14 keV \[^{[33]}\]. Different lower bounds depend on several issues, including which subset of Lyman alpha-forest data is taken into account.

Another constraint on potential dark matter sterile neutrinos comes from the observation of X-rays originating in galactic clusters. Such regions of the universe should be overdense with warm dark matter heavy neutrinos, which can be directly observed via their radiative decay \(^{[6]}\). Bounds from X-ray observations have been summarized very recently \[^{[24]}\]. Combining the results of \[^{[24]}\] and Fig. 4, we find that for lightest neutrino masses larger than \(10^2\) eV, such bounds can only be avoided for \(m_1 < 100\) eV, where large scale structure constraints on warm/hot dark matter are severe. This qualitative analysis indicates that seesaw sterile neutrinos cannot simultaneously fit the LSN D data and serve as cold dark matter.

On the astrophysics side, the most severe constraint on light, sterile neutrinos is provided by the observation of electron (anti)neutrinos coming from SN1987A. The current analysis consists of comparing the model-dependent neutrino flux at the surface of the neutrinosphere with that detected on Earth. Large sterile neutrino mixing and mass would result in modification/depletion of the detected neutrino signal (for a recent detailed discussion, see \[^{[25]}\]). Although only twenty neutrinos were observed in this event, one can still place bounds on sterile-active neutrino mixing. As far as LSN D sterile neutrinos are concerned, these bounds are still weaker than those obtained by the null short baseline oscillation experiments \[^{[23]}\] and therefore already accounted for in our analysis. Heavier right-handed neutrinos can, however, be excluded by SN1987A neutrino data. Fig. 4 depicts the region of parameter space excluded by SN1987A data (region to the right of solid, diagonal line). This bound is set by \(m_1 > 0.22\) keV \[^{[31,32]}\]. See also \[^{[23]}\]. A coating to Fig. 4, supernova bounds force the seesaw scale to be below a few keV for \(m_1\) values above 0.01 eV.

### C. Pulsar Kicks

Pulsars are born from the gravitational collapse of the iron core of a massive star. These core collapse supernovae are an excellent source of neutrinos, producing all (active) iron core. Current observations point to the fact that some pulsars move with peculiar velocities much greater than those expected from an asymmetric supernova explosion mechanism. Quantitatively, current three-dimensional models yield velocities up to 200 km/s \[^{[30]}\], while pulsars moving at speeds as high as 1600 km/s have been observed.

Since roughly 99% of the approximately \(10^{53}\) ergs of energy released in a core collapse supernova is in the form of neutrinos, it is reasonable that neutrino physics provides a solution to this anomaly. At these rates, a small \((1 - 3)\%\) of this energy in neutrino emission can account for the observed large pulsar velocities. Neutrinos are always produced asymmetrically in the polarized medium of the proto-neutron star, due to the left-handed nature of their interactions. Unfortunately, asymmetric production cannot solve this problem because the associated medium densities are such that neutrinos undergo multiple scattering within the star's interior, eventually eluding out of an effective surface, called the neutrinosphere, with all initial asymmetric mixed away. Several distinct mechanisms have been formulated to sidestep this fact. Special examples include the existence of large neutrino magnetic moment events that have been explored in \[^{[40]}\], and can be tested in next generation neutrino experiments (see \[^{[41,42,43]}\]). Proposed solutions also exist, which utilize standard three-avorn neutrino oscillations, where and appearing between their neutrinosphere and the larger neutrinosphere, can stream unhindered out of the star \[^{[44]}\]. This solution is, however, currently disfavored by terrestrial oscillation experiments.

We concentrate on the case of oscillations into sterile neutrinos, which can proceed in various ways, depending on the mass and coupling of the relevant neutrinos as well as the properties of the collapsing star, including its density and magnetic field. Following \[^{[45]}\], we separate and analyze these within three distinct categories. One requires the existence of a keV-scale sterile neutrino with very small couplings to the active avors, of the order \(10^{-4}\) \(10^5\), especially if light sterile neutrinos are them produced in the early universe. Under these circumstances, if seesaw neutrinos are to play the role of the sterile neutrinos responsible for pulsar kicks, \(^{[46]}\) \(m_{\nu_i} \approx 10^6\) eV. This implies \(m_{\nu_i} > 10^3\) eV and is only compatible with a hierarchical active neutrino mass spectrum and very light \(m_{\nu_i}\) as identified in \[^{[47]}\].

Here, instead, we will concentrate on identifying solutions that will address pulsar kicks and the LSN D anomaly. According to the discussion in the previous subsection, the mostly sterile neutrino masses \(m_4\) and \(m_5\) are constrained to be less than 10 eV so that a 3+2 solution to the LSN D anomaly can be obtained from the seesaw Lagrangian. The heaviest neutrino mass \(m_6\) is unconstrained, so we are free to vary it as needed in order to attack the pulsar peculiar velocity issue? Naively, the fraction of \(^{[46]}\) \(m = e; \gamma\) in \(m_6\) is expected to be of the order
In scenario 1, the pulsar kick is produced via an active (sterile M SW resonance in the core of the proto-neutron star at large densities, greater than $10^{14}$ cm$^{-3}$, and magnetic fields, near $10^{16}$ G [46]). The effective neutrino mass potential in material polarized by a strong magnetic field contains a term proportional to $k \cdot B = k_j [43,46]$, where $k$ is the neutrino's three-momentum and $B$ is the local magnetic field. Clearly the M SW resonance occurs at a radius that depends on $k \cdot B = k_j$, the relative orientation of the neutrino momentum and magnetic field. Sterile neutrinos produced at smaller radii (higher temperatures) carry greater average m momentum than those produced at larger radii (lower temperatures), yielding an asymmetric m momentum distribution of emitted neutrinos. This asymmetry is capable of producing the observed pulsar kicks, in the direction of the magnetic field, when the m mass and coupling of the sterile state is near 8 keV and above $1.5 \times 10^5$, respectively [45]. We found the best fit to the LSND data (using $\theta$ and $\phi$) and pulsar kicks (using $\phi$) and $m_6 > 5$ keV. The $\theta$ and $\phi$ best fit values are depicted in Fig. 2. This solution is strongly disfavored by the observation of neutrinos from SN 1987A. The fact that $\theta$ is much larger than the other two active (sterile mixing angles is due to the fact that $\theta$ and $\phi$ are constrained by LSND data to be much smaller than naive expectations (see Eq.[46]). In order to reduce $\theta$, one would have to either reduce $m_1$ by an order of magnitude which renders the $3+2$ solution to oscillation data very poor (or increase $m_6$, which would only push $\theta$ deeper into the region of parameter space ruled out by SN 1987A. One can, however, find solutions to LSND data where $\theta$ could pose as the sterile neutrino that explains why pulsar peculiar velocities are so large (see Eqs.[47,48]).

Scenario 2 also relies on a direction-dependent M SW resonance, this time occurring outside the core where the m matter density and temperature are much lower. Here, both the active and sterile neutrinos are free to stream out of the star. The departing active and sterile neutrinos still have a small interaction cross-section, $G_F^2 E^2$, and can therefore deposit energy and m onto the star's gravitationally bound envelope proportional to the m matter it transverses. Via the direction-dependent resonance, neutrinos in the direction of the m magnetic field gain an active longer, deposit more m onto the star, and thus, kick the star forward. The observations can be explained in this case with a smaller sterile m mass and larger active (sterile coupling near 4 keV and $4.5 \times 10^5$, respectively [45]. In the case of our LSND data, the data, we can constrain one of $\theta$ or $\phi$ to lie inside region 2. The other $\theta$ or $\phi$ (or $\theta$), however, must be constrained to be larger, and lie inside region 3.

Scenario 3 proceeds through o resonance production of the sterile neutrino in the proto-neutron star core [45]. The amplitude for sterile neutrino production by a weak process is proportional to $U_{6e}^2$, the e active m mixing angle between the heavy m and eigenstate and the o eigenstate. Initially, this quantity is very small due to m matter effects in the dense core. The e active m potential in the star's interior is quickly driven to zero in the presence of sterile neutrino production by a negative feedback mechanism. If this occurs in a time less than the diffusion time scale for the active neutrinos, approximately $3(10)^3$, the m mixing angle will reach its vacuum value [45]. The sterile neutrinos will then be produced and emitted mixing asymetrically and thus, kick the pulsar to large velocities. Lower limits on the vacuum m and m mixing angles are derived by requiring that the o resonance time scale (inversely proportional to $m_4 \sin^2 2 \theta_e$) for the evolution of the m potential to zero be less than about ten seconds. This places the sterile m mass and m mixing at approximately $1$ keV and above $5 \times 10^5$, respectively. Since all three active neutrinos are present in equal abundances and all contribute to the e active m potential, the m mixing angle in question is not any particular $U_{6e}$. Rather, it is the angle $\theta_6$ associated with the projection of $\theta_e$ onto the space spanned by $\theta_e$ and $\gamma = 2 U_{6e}^2 + U_{2e}^2 + U_{3e}^2$. From Eq.[46A] we see that $\gamma = m_4 m_6$ up two corrections due to the non-unitarity of V and active neutrino m mixing angles. This is independent of m mixing angles, and therefore cannot be tuned to be small. Our best fit $t_\mu^\pm$ solution is depicted in Fig. 2 by a star. It turns out that $U_{6e}$ have very similar values for $\gamma = \theta_e$; $\gamma$. In order to evade the SN 1987A constraint, we were forced to pick $m_1$ values close to lower bound of our $3+2$ LSND data $t_\mu^\pm$ ($m_1 = 0.22$ eV), so that $\theta_{1e}^\pm, \theta_{2e}^\pm, \theta_{3e}^\pm$ are close to the low end of the allowed range in Table I.
D. Supernova Nucleosynthesis

Core collapse supernova are believed to produce the observed heavy element (A > 100) abundance through the r-process, or rapid neutron capture process. Here we briefly review this mechanism (see [5]) for a comprehensive review, as well as its facilitation by the addition of active (sterile neutrino) oscillations [52]. This scenario begins in the neutrino-driven wind; that is, the wind of ejected nucleons driven by neutrinos radiated from the cooling proto-neutron star. The maintenance of equilibrium among neutrons, protons, and electron (anti)neutrinos in neutrino capture processes leads to a neutrino-rich environment. As the wind propagates, it cools enough for all free protons to bind into particles. In the ideal r-process picture, the wind cools further these particles bind into intermede size seed nuclei which later undergo neutron capture to form the observed heavy r-process elements.

This ideal scenario is dampened by the large number of electron neutrinos present at the stage of particle formation. These will capture on the free neutrons, converting them to protons, which in turn will fuse to make more particles. The result is a very small free neutron to particle ratio, conditions unfavorable for r-process element formation. This is known as the effect and must be circumvented to produce the correct distribution of heavy elements. A clear solution to this problem is to reduce the number of electron neutrinos present at this stage, which can be accomplished by resonant $\beta^+\beta^-$ conversion [53].

The sterile neutrino solution to the r-process mechanism is modeled and to the data in reference [53], including the effects of relevant nuclear physics and additional neutrino oscillations in the star’s envelope. The analysis is expanded in [54] with the inclusion of electron cycling of the produced heavy elements. The analysis indicates the need for an eV-scale sterile neutrino with an allowed parameter space much larger than that constrained by LSND. By itself, the requirement of successful r-process in supernovae only weakly constrains the light neutrino mass scale to be greater than $10^{-2}$ eV and $10^{-3}$ eV for a 1 eV and 10 eV sterile neutrino, respectively. With regard to the LSND results, it has been demonstrated that the 3 + 1 oscillation scenario is within this parameter space [54]. Considering that the mass-squared differences and mixing angles for the fourth mass eigenstate, which makes up most of the lightest sterile neutrino, is very similar between the 3 + 1 and 3 + 2 case [54], it is reasonable to conclude that resonant conversion will also be within this scenario. Even oscillations into the heaviest state can potentially solve this anomaly if the neutrino driven wind expansion time scale is sufficiently small. 0.1 sec. To conclude this section we note that, although the sterile neutrino solution to the supernova nucleosynthesis problem is well within our seesaw framework, it adds no additional constraints, and therefore does not increase the predictability of our scenario.

IV. OTHER PROBES OF THE SEESEAW ENERGY SCALE

Here we survey other existing and future probes of light sterile neutrinos. As opposed to the previous cases, these probes are perfectly consistent by themselves. That is, extra heavy neutrinos are not required to solve problems within the system. However, their addition can lead to large modifications to the outcome of such experiments, thus rendering the eV-scale seesaw scenario testable. Specifically, we consider bounds from tritium beta-decay and neutrinoless double-beta decay. Observations in all of these areas have already yielded useful constraints on sterile neutrinos, and the situation is expected to improve in the next few years.

A. Tritium Beta-Delayed Decay

The endpoint of the electron energy spectrum in the beta-decay of tritium is a powerful probe of nonzero neutrino masses. This results from the decay kinematics of the system, which is essentially modulated by the presence of a massive neutrino. The nonzero neutrino mass effect can be understood almost entirely from the phase space distribution of the emitted electrons, and is therefore model independent. Existing beta decay experiments extract limits on an effective electron neutrino mass $m^2 = 1.3 \times 10^{-4} \text{ eV}^2$ [55], provided that the neutrino masses are smaller than the detector energy resolution. Currently the most stringent bounds on $m^2$ are $(2.3)^3 \text{ eV}^2$ at 95% confidence from the Mainz experiment [56] and $(2.5)^3 \text{ eV}^2$ at 95% confidence from the Trojan experiment [57]. In the next few years, the KATRIN experiment should exceed these limits by nearly two orders of magnitude, probing down to $(0.2)^3 \text{ eV}^2$ at the 90% confidence level [58]. Note that naively compute this effective mass for the best $m^2$ mixing

$^{2}$ In this mechanism the effective matter potential, which depends on the number of electrons, positrons, and neutrinos, varies wildly as a function of distance from the core. Along this radial direction there are three relevant $\text{MSW}$ resonant conversions that must be tracked and understood: $\beta^+\beta^-$ and $\beta^+\beta^-$. See [5] for more information.
parameters obtained in the previous section. In this case, we expect a keV seesaw neutrino to contribute to $m^2$ by a huge amount: $m^2 = U_{ei}^2 m_6^2$ so that it would be excluded by the current precision measurements of tritium beta-decay for $m^2 \approx 10^{-4}$ eV. This is clearly an incorrect treatment of the physics. As pointed out in, for example, [5], the existence of a heavy neutrino state would produce a kink in the electron energy spectrum of size $j_{ei} E_0$ at an energy $E_0 - m_1$ as well as a suppression of events at the endpoint of order $1 \times 10^{-3}$ eV is the endpoint energy of tritium beta-decay. 

Figure 3 depicts $S = S_0$, where $S$ is the electron energy spectrum obtained assuming three mostly active, degenerate neutrinos with $m = 0.1$ eV and one mostly sterile neutrino $m_1$ with various masses $m_1$ and mixing angle $U_{ei} = m = m_1$, while $S_0$ is the spectrum associated with massless neutrinos. One can readily observe the kink in the spectrum above $m_1$. For energies above $E_0 - m_1$, the impact of the sterile state is to remove around $1 \times 10^{-3}$ of the $\beta$-rays from spectrum. This is most significant between $E_0 - m_1$ and $E_0 + m_1$ mass of the active neutrinos. For energies below $E_0 - m_1$, the spectrum agrees with that obtained from the emission of one active neutrino with mass-squared $m^2$.

We estimate the sensitivity of future tritium beta-decay experiments to the emission of one heavy state by considering the ratio between the number of electrons with energies above $E_0 - m_1$ and in the case of massless neutrinos,

\[
R(U_{ei} M_R) = \frac{Z_{e0} E_0}{E_0} \frac{dN}{dE} (0) + 1 \frac{Z_{e0} E_0}{E_0} \frac{dN}{dE} (0) + \frac{Z_{e0} E_0}{E_0} \frac{dN}{dE} (0) \quad (IV.12)
\]

where $dN/dE$ is the energy distribution of $\beta$-rays, which depends on the neutrino mass $m_1$. This expression can be easily generalized for more than one heavy neutrino. The advantage of using the ratio above is that potential systematic uncertainties and normalization effects can be safely ignored. An experiment is sensitive to a massive neutrino state if it can distinguish $R$ from unity, a determination that should be limited by statistics due to the very low $\beta$-ray flux in the high-energy tail of the electron spectrum.
In order to compute $R$, we use an analytic expression for Eq. (IV.12), which exists provided that one neglects nucleon recoil in the decay. Fig. 4 depicts constant $R$-contours in the $U_{ei}$-$m_1$ plane. Contours were computed for $E = 25$ eV, in order to allow one to easily compare our results with the sensitivity estimates of the KATRIN experiment. After data-taking, KATRIN is expected to measure $R$ at the 0.1% (1% level) (lightest grey region). Its sensitivity is expected to be $m^2_{ee} > 0.2$ eV at the 90% confidence level. This can be extracted from the plot by concentrating on the $U_{ei} = 1$ line. Note that while the expected energy resolution for KATRIN is of order 1 eV, the expected number of signal events above $E_0 = 1$ eV is insusceptible (both in absolute terms and compared with expected number of background events), so that most of the sensitivity to nonzero neutrino masses comes from analyzing the shape of the electron spectrum in the last tens of electron-volts. A larger “window” would suffer from increased systematic uncertainties, so that $E = 25$ eV is representative of KATRIN’s optimal reach.

The shape of the constant $R$ contours is easy to understand. As already discussed, for $m_1 > E$, the effect of the right-handed neutrinos is to reduce the spectrum in an energy independent way by $1/j_{ei}$, while for $m_1 < E$, states with the same effective mass-squared $m_{ei}^2/j_{ei}$ produce the same effect in tritium beta-decay so that the diagonal lines coincide with lines of constant $m_{ei}^2/j_{ei}$.

A more sensitive approach would be to bin the last tens of eV of the “data” into 1 eV bins, and then the distribution of a massless neutrino hypothesis. For the values of the parameters in which we are interested, we find that one 25 eV bin yields roughly the same sensitivity to nonzero neutrino masses as twenty 1 eV bins for large masses and small mixing angles. For smaller masses and larger mixing angles, a “binned” analysis should be sensitive to effects which are localized in individual bins (such as “kinks”). A new recent estimate of the sensitivity of KATRIN to heavy, sterile neutrinos can be found in [55].

Fig. 4 also depicts the loose upper bound for $U_{ei} = \frac{p_{i=1}}{m_i}$ as a function $m_1$, for $m_1 = 0.32$ eV and $m_1 = 0.01$ eV. For $m_1 > 0.1$ eV, KATRIN should be sensitive to $M_R$. 1 keV, while for $m_1 \approx 0.01$ eV (the solar mass scale) KATRIN should be sensitive to $M_R \approx 10$ eV and $M_R \approx 100$ eV, where here we assume that all right-handed neutrino masses are of order $M_R$. In the case of seesaw parameter sets that $t$ the LSND data with a 3+2 neutrino spectrum (see Eq. (III.3)), expectations are high as far as observing a kinematical neutrino mass effect at KATRIN, in spite of the fact that the

---

**Fig. 4:** Contour plot of constant $R$, as defined by Eq. (IV.12), assuming an energy window $E = 25$ eV. The solid (dashed) line corresponds to $m_i = m_1$, a naive upper bound for $U_{ei}$ for $m_1 = 0.3$ eV (0.01 eV). The circles correspond to $U_{ei}$ for the three most sterile states obtained by our "t" to other neutrino data, Eq. (IV.12). See text for details.
to LSND data requires $U_{ee}$ and $U_{e3}$ to be "abnormally" low. Fig. 3 depicts $U_{ei}$ and $m_1$ values for the heavy neutrinos (open circles). The contribution of the heaviest of the two LSND $\nu_e$-related sterile neutrinos is of order the 
Katrin sensitivity, while the active contribution itself, which leads to $m^2_1 = \sum_{i=1,2,3} |U_{ei}|^2 m_i^2$ is already within the Katrin sensitivity range, given that large $m_1 > 0.22$ eV values are required by our $3+2$ LSND \t". The effect of $\bar{\nu}_e$ is small if $m_3$ is larger than 1 keV (required if one takes the "pulsar kicks" hint into account), but would be very significant if $m_3$ were less than 1 keV.

B. Neutrinoless Double-Beta Decay

If the neutrinos are Majorana fermions (as predicted in the case of interest here, lepton number is no longer a conserved quantity. The best experimental probe of lepton number violation is the rate for neutrinoless double-beta decay. This process, which violates lepton number by two units, is currently the subject of intense search \cite{60}. If neutrino masses are the only source of lepton number violation, the decay width for neutrinoless double-beta decay is

$$\Gamma = \frac{U^2_{ei} m_i}{M (m^2_i + Q^2)^2}$$

where $M$ is the relevant nuclear matrix element and $Q^2 > 50^2$ MeV$^2$ is the relevant momentum transfer. In the limit of very small neutrino masses ($m^2_i \sim Q^2$), $\Gamma$ is proportional to an effective neutrino mass $m_{ee}$.

$$m_{ee} = \frac{X^n}{\sum_i U^2_{ei} m_i}$$

The sum is over all light neutrino mass eigenstates. In the case of a low-energy seesaw, when all $m_i, i = 1; \ldots; 6$ are much smaller than $Q^2$, it is easy to see that $m_{ee}$ vanishes \cite{12}. The reason for this is that, in the weak basis we are working on (diagonal charged-lepton and charged weak-current), $m_{ee}$ is the $ee$-element of the neutrino mass matrix, as defined in Eq. 12. One can trivially check that, by assumption, not only does $m_{ee}$ vanish, but so do all other $m_{ij}$, $i \neq j$. Note that this result does not depend on the fact that we have been assuming all elements of the neutrino mass matrix to be real \cite{61}.

For heavy $\nu_i$ neutrinos, $U^2_{ei} m_i$ no longer captures the dependency of $\Gamma_0$ on the exchange of $\nu_i$. For $m^2_i \sim Q^2$, instead, the dependency on neutrino exchange is proportional to $U^2_{ei} m_i$. If this is the case, the overall contribution (including all heavy and light states) is no longer proportional to $m_{ee}$ but, instead, can be qualitatively expressed as a function of an effective $m_{ee}^e$.

$$m_{ee}^e = \frac{X^n}{Q^2 \sum_i U^2_{ei} m_i}$$

The approximation $\Gamma_0 / m_{ee}$ is good as long as one can neglect the dependency of $M$ on $m_i$ and is not expected to be a great approximation when $m^2_i \sim Q^2$. Nonetheless, $m_{ee}^e$ still qualitatively captures the behavior of $\Gamma_0$ as a function of the sterile neutrino mass and studying its behavior is sufficient for our ambitions in this discussion.

Fig. 4 depicts $m_{ee}^e$ for our best $3+2$ LSND solution (see Sec. IIIA), as a function of the unconstrained $m_3$. As advertised, $m_{ee}^e$ vanishes for $m^2_3 \sim Q^2$. The figure also depicts the "active only" value of $m_{ee}^e = \sum_{i=1,2,3} |U_{ei}|^2 m_i$. Even in the limit $m^2_3 \sim Q^2$, there is still partial cancellation between the mostly active and mostly sterile LSND states. This is a feature of the Lagrangian we are exploring here, and is not in general observed in other scenarios with light sterile neutrinos that are used to solve the LSND anomaly.

Currently, the most stringent limits on these effective mass come from the Heidelberg-Moscow experiment \cite{2}, where they set $m_{ee} < 0.51$ eV at 99% confidence. In the near future, experiments aim to reach down to $m_{ee} = 10^{-2}$ eV \cite{60}. A signal would rule out a seesaw scale below tens of MeV. On the other hand, if we were to conclude that the neutrino masses are quasi-degenerate (through, say, a signal in tritium beta-decay) and if the LSND 3+2 solution were experimentally confirmed, a vanishing result for $m_{ee}$ could be considered strong evidence for a very small seesaw scale. If this were the case ($m_{ee}$ zero, large active neutrino masses), it would also be very reasonable to conclude that neutrinos are Dirac fermions. Distinguishing between the two possibilities would prove very challenging indeed. It is curious (but unfortunate) that in a low energy seesaw model, the neutrinos are Majorana fermions, but all "standard" lepton-number violating observables vanish, given that their rates are all effectively proportional to $m_i$.
V. CONCLUDING REMARKS

The "New Standard Model" (equal to the "old" Standard Model plus the addition of three gauge singlet Weyl fermions) is, arguably, the simplest extension of the SM capable of accommodating neutrino masses. This Lagrangian contains a new dimension-full parameter: the right-handed neutrino mass scale $M$, which must be determined experimentally. Unlike the Higgs mass-squared parameter, all $M$ values are technically natural given that the global symmetry of the Lagrangian is enhanced in the limit $M \rightarrow 0$.

Very large $M$ values are theoretically very intriguing, and have received most of the attention of the particle physics community. There are several strong hints that new phenomena are expected at the electroweak breaking scale $10^2$ GeV, the grand unified scale $10^5$ GeV, and the Planck scale $10^8$ GeV, and it is tempting to associate $M$ to one of these energy scales. Furthermore, large $M$ values provide a mechanism for generating the matter antimatter asymmetry of the Universe [34]. Of course, large $M$ values are experimentally very frustrating. It may ultimately prove impossible to experimentally verify whether the New Standard Model is really the correct way to describe Nature.

Here, we explore the opposite end of the $M$ spectrum, $M \approx 1$ keV. Such values are phenomenologically very intriguing, given that all $M$ values imply the existence of light sterile neutrinos that mix significantly with the active neutrinos and can potentially be directly observed. Furthermore, there are several experimental and astrophysical phenomena that are best understood if one postulates the existence of light, moderately mixed sterile neutrinos. We find that by requiring all three right-handed neutrino masses to be less than a few keV, we can simultaneously explain all neutrino oscillation data, including those from LSND, explain the large peculiar velocities of pulsars, and explain the production of heavy elements in supernova environments. Our analysis also provides constraints for the active neutrino oscillation parameters, most strongly to the lightest active neutrino mass. All successful parameter sets that account for these LSND data require $m_1$ to be large (1 eV), and the best $t^m$ requires all active neutrino masses to be quasi-degenerate.

On the negative side, low $M$ values are, theoretically, rather puzzling. In order to obtain the observed light neutrino masses, neutrino Yukawa couplings are required to be much smaller than the electron Yukawa coupling, and
it is tempting to believe that such small numbers are proof that a model satisfying understanding of fermion masses must exist. Furthermore, there is no more an option (see, however, [44]). Finally, the fact that \( M \) is naively unrelated to other mass scales can also be perceived as disheartening, but in our opinion, should be interpreted as evidence that there is no one to the lepton sector than \( M \) meets the eye.

Regardless of one's preference for a high or low seesaw energy scale, and independent of whether the data from LSND and the astrophysical observations discussed above have anything to do with sterile neutrinos, our main point is that the demonstration that \( M \) is an experimental issue. In the near/far-decay future, low energy seesaw scales will be probed by several experiments; most prominently measures of the end-point of tritium beta-decay, the \( M \text{BooNDE} \) experiment, searches for neutrinoless double-beta decay and, if we get lucky, the detection of neutrinos from a nearby supernova explosion. For example, that KATRIN should be sensitive to seesaw energy scales below\( \text{GeV} \) if all right-handed neutrino masses are similar, while null results from \( \text{MBooNE} \) would severely constrain right-handed neutrino masses below\( \text{several eV} \). We conclude by pointing out that larger (but still small) values of \( M \) are much harder to constrain. For\( \text{GeV} \) sterile neutrinos, typical active/sterile mixing angles are \( 10^{-1} \), probably too small to observe in particle physics processes. It is frustrating (and, we hope, ultimately false) that we seem to be unable to experimentally distinguish \( 1 \text{ GeV} \) from \( 10^6 \text{ GeV} \) ...

Acknowledgments

We thank Irina Mocioiu for comments on how the pulsar kick requirements extend toward the \( s > 0.3 \) region, and Michel Sorel for discussions regarding \( 3+2 \) to the neutrino oscillation data. JJ would also like to thank the students and lecturers of the TASI 2006 summer school for useful discussions of this manuscript and many related physical concepts. This work is supported in part by the DOE grant # DE-FG02-91ER40684.
